AT the ninth meeting of the Executive Council of the International Institute of African Languages and Cultures, held in Paris under the presidency of the chairman, Lord Lugard, on May 27–29, it was announced that the Rockefeller Foundation had promised a grant to the Institute, not to exceed £10,000 per annum, for a period of five years. Of this amount, £5000 per annum is a fixed grant. The remaining £5000 will be paid on the basis of £1 for each £2 obtained from other sources. The grant is for research work; and with this amount at its disposal the Institute will be enabled to prosecute a regular scheme of organised research, such as it has always contemplated since its foundation. A programme has already been discussed by the Executive Council. It is now being elaborated for submission at the next meeting of Council to be held in Paris in October. This generous recognition of the importance of the problems of Africa, of which the Rockefeller Foundation has shown itself convinced on previous occasions, should stimulate possible benefactors to ensure that the full amount of the grant may be made available for studies bearing upon what is held by many to be the gravest of the problems which will confront modern civilisation in the future—the relation of the white and the black races.

THE sixth annual meeting of the British Association of Commercial Seed Analysts was held on July 25 at the National Institute of Agricultural Botany, Cambridge, the president, Mr. N. L. Dickson, being in the chair. The report of the past year showed that a considerable amount of work has been accomplished, particularly interesting results having been obtained by co-operative work among members in the testing of exceptionally difficult seeds. Six papers, including valuable notes on "New Crop Germinations", have been published and an exchange of papers made with various Colonial and American departments of agriculture and the American Seed Analysts' Association. All publications received have been added to the library and are available to members on loan; further, it is hoped to issue summaries of such papers, in addition to extracts from the *News Letter* (the official organ of the Association of Official Seed Analysts of North America). Papers on the question of the germination of damaged seeds, read by Mr. F. H. G. Neale and Mr. W. Hallam Harding, aroused considerable interest and tended to confirm the opinion that many so-called damaged seeds will eventually produce normal plants. It was announced that Dr. Nelson, of the Royal Botanic Gardens, Edinburgh, a former president of the Association, has kindly offered to help members with any difficulties that might arise with unusual species, and the hope was expressed that members will not hesitate to communicate the results of their research work, experiences, or difficulties to the secretary Mr. F. H. G. Neale, "Emmandee," Hawthorn Gardens, Reading, as by this means the Association can prove of the greatest benefit to all its members.

THE South African Museum, in Cape Town, is to be congratulated upon the additions to its capacity made during the year through the aid of the Union Government. Storage and workroom accommodation has been increased, and the erection of a new wing and the taking over of rooms occupied by the Art Gallery will give much-needed opportunity for an adequate exhibition of the animals of South Africa. We trust that systematic zoology, which after all is but one aspect of a big subject, will not claim all the new space, and that a definite allocation may be made of room to illustrate the general teachings of natural science. Another side of the activities of this Museum deserves commendation. It sends annual expeditions to the country for the observation and collection of the native fauna, and in its journal, the *Annals of the South African Museum*, it publishes contributions to the knowledge of the animals of South Africa which, for quality and quantity, equal, and indeed exceed, the products of many much wealthier institutions. The abstract of accounts, which appears at the end of the Report for 1930, shows that the total grants made to the Museum fall short of £8000, and of this sum, more than £400 was devoted to the publishing of scientific results, evidence of the research enthusiasm of the staff.

THE Imperial Bureau of Fruit Production, East Malling, Kent, has produced the first number of a journal, *Horticultural Abstracts*, that it is proposed to issue quarterly. The annual subscription, five shillings, is very reasonable, so that this publication may appeal to a number of horticulturists and students of horticulture. On the other hand, it is difficult to know where scientific work of a biological character definitely ceases to be of interest to horticulture, so that many workers will probably prefer the bigger and more expensive *Biological Abstracts* now issued by the Union of American Biological Societies, which includes a special section for abstracts of a definitely horticultural character. In the present number of the new journal, 108 papers are dealt with; the abstracts, whilst commendably brief, seem to give a very clear idea of the general character of the papers. It is certain, however, that four issues upon this scale will not cover comprehensively the annual output of general scientific work of interest to the worker in horticulture.

ONE important outcome of the Conference of Empire Surveyors in 1928 has been the foundation of the quarterly *Empire Survey Review*, of which the July issue is the first. It is published at 3*s*. a number by the Crown Agents for the Colonies. The issue opens with an article by Mr. O. G. S. Crawford on primitive English landmarks and maps, which traces some of the influences that led to the division of lands and the institution of boundaries up to the fifteenth and sixteenth centuries. Another article, by Capt. D. R. Martin, describes the ingenious map-mounting machine which for a few years has been used by the Ordnance Survey in place of hand mounting or of the use of linen-backed paper in the printing room. There are also several shorter articles on technical problems of survey, as well as reports on various Empire survey departments.

ON Aug. 6, Mr. J. A. Mollison made a forced landing on English soil near Pevensey at 1.35 P.M., thus reducing the time for the flight between Australia and England by about two days. The actual time taken for the flight was 8 days 20 hours 19 minutes, the previous record, made by Mr. C. W. Anderson Scott, being 10 days 22 hours. The flight was an adventurous one, and Mr. Mollison experienced many difficulties, due chiefly to vagaries of the weather, which caused a certain amount of delay. The distance covered was about 10,000 miles, thus giving an average of about 1100 miles a day. The machine used was a Gipsy Moth, and, apart from extra petrol tanks, was a standard machine used for training amateur pilots. The engine was a Gipsy II. (120 h.p.).

IT is with regret that we announce the death, on Aug. 6, of Prof. Archibald Barr, F.R.S., who was formerly Regius professor of civil engineering and mechanics in the University of Glasgow, and past president of the Royal Philosophical Society of Glasgow and of Section G of the British Association. Prof. Barr was seventy-six years of age.

THE following appointments have recently been made by the Secretary of State for the Colonies: Mr. A. J. W. Hornby, agricultural chemist, Nyasaland, to be assistant director of agriculture, Nyasaland; Mr. A. C. Miles, provincial superintendent of agriculture, Gold Coast, to be assistant director of agriculture, Gold Coast; Mr. R. O. Williams, superintendent, Royal Botanic Gardens, Trinidad, to be economic botanist, Trinidad; Mr. G. F. Clay, senior agricultural officer, Uganda, to be deputy director of agriculture, Uganda.

IT will be remembered that the Faraday Society has convened a Colloid Committee to organise periodical meetings for the discussion of subjects connected with colloid science. The first meeting was held in Cambridge last year to discuss "Colloid Science Applied to Biology". Arrangements are now on foot for the second meeting, which will be held in Manchester in the autumn of 1932 to discuss "Textile Materials. their Components and Related Topics". A special organising committee has been convened to draft the programme of the meeting.

THE new edition of the "Guide to Current Official Statistics of the United Kingdom" (H.M. Stationery Office, 1*s*.) has now appeared. This annual volume is of value to all workers who have occasion to use any of the statistical reports of various Government departments. A glance at its pages shows the wealth of material available. The greater part of the 320 pages is a detailed subject index with references to the numbers of the publications, which are listed also in numerical order under the various departments.

WE have received from Messrs. Watson and Sons (Electro-Medical), Ltd., Sunic House, 43-47 Parker Street, Kingsway, London, W.C.2, two new catalogues dealing respectively with diathermy apparatus and equipment for X-ray therapy. In each a brief introduction is given on the principles of the apparatus employed, followed by lists of outfits and accessories which experience has shown fulfil requirements. These include 'Sunic' condensers and spark gaps, induction coil apparatus, current generators, tubes and valves, filters and applicators, Greuz ray apparatus for treatment of skin affections, and protective materials.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—Two marine biologists (one a planktologist and one a benthos specialist) in the Marine Fisheries Laboratory of the Egyptian Government Coastguards and Fisheries Service, Alexandria—The Royal Egyptian Legation, 75 South Audley Street, W.1 (Aug. 20). A teacher of handicraft (woodwork, metalwork, and technical drawing), and an assistant master to teach, principally, elementary science and mathematics, at the Junior Technical School of the Castleford, Normanton, and District Mining and Technical Institute, Whitwood—M. G. Swaine, Education Offices, Castleford (Aug. 21). A graduate assistant at the Abertillery Mining and Technical Institute, and an engineering instructor at the Ebbw Vale Mining and Technical Institute—The Director of Mining Education, County Hall, Newport, Mon. (Aug. 24). A demonstrator of anatomy at the Royal Veterinary College—The Secretary, Royal Veterinary College, Camden Town, N.W.1 (Aug. 31). Two research assistants at the Institute of Agricultural Engineering, Oxford University, with special qualifications in, respectively, physics and engineering—The Secretary, Institute of Agricultural Engineering, 37A St. Giles, Oxford (Aug. 31). A male assistant curator of the Leeds Museums—The Committee Department, Town Clerk's Office, 26 Great George Street, Leeds (Sept. 9). A university reader in pathology at Westminster Hospital Medical School—The Academic Registrar, University of London, S.W.7 (Sept. 18). A William Julius Mickle fellow of the University of London—The Academic Registrar, University of London, South Kensington, S.W.7 (Sept. 30). A rector of Glasgow Academy—The Secretary, Glasgow Academy, 190 West George Street, Glasgow (Oct. 1). A Scottish medical secretary of the British Medical Association—The Medical Secretary, British Medical Association, Tavistock Square, W.C.1 (Oct. 1). A sixth form chemistry master at the Crypt School, Gloucester—The Headmaster, Crypt School, Gloucester.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Velocity of Deep Currents in the South Atlantic.

In view of the great difficulty with which the speed of a deep current is measured, the following investigation is of considerable interest. The observations on which it is based were made by Mr. H. F. P. Herdman and me in the R.R.S. *Discovery II.* during the recent passage home from the Antarctic.

Vertical sections were made along the 30th meridian from 60° S. to 15° N. showing the distribution of temperature, salinity, oxygen, phosphate, nitrate, and nitrite content, and of the hydrogen-ion concentration. They show that the surface water found in the region of the West Wind Drift between 41° S. and 50° S. sinks rapidly below the surface along its convergence with the warmer sub-tropical water in 41° S. After sinking, it spreads northwards as a poorly saline layer between the depths of 500 and 1500 metres and covers the whole of the South Atlantic. It is then generally known as Antarctic Intermediate Water. As it sinks, it carries with it large quantities of dissolved oxygen, which are used up by the living animals and by the oxidisable matter in the water as it flows northwards. The accompanying table shows the depths of the minimum salinity values which represent the nucleus of the Antarctic intermediate layer, and also the oxygen content of the water in these depths, for different latitudes.

Latitude.	Depth of Minimum Salinity. Metres.	Oxygen Content in the Salinity Minimum. C.c./litre.
46° 42·5′ S.	330	6·02
43° 08′ S.	410	5·94
38° 10·5′ S.	800	5·45
34° 08′ S.	910	5·19
31° 16·25′ S.	940	4·86
26° 06·5′ S.	850	4·59
21° 13′ S.	850	4·24
15° 37′ S.	700	4·08
09° 47′ S.	750	3·50
03° 17·75′ S.	690	3·36
02° 59·25′ N.	740	3·06
08° 54·25′ N.	800	2·18
14° 27·25′ N.	800	2·37

Owing to differences in the temperature and the quantity of phytoplankton, the amount of dissolved oxygen in the surface of the West Wind Drift varies from season to season, and the amount which sinks and flows northwards must also vary. Fig. 1 shows the oxygen content of the Antarctic Intermediate Water plotted against latitude. It will be seen that the oxygen content decreases rapidly in the water as it flows northwards, but the points which represent the determinations lie on a curve which shows well-defined maxima and minima.

The water in the West Wind Drift has its maximum oxygen content in the spring, and the maxima on the curve represent the oxygen content in the water which has left the surface in successive years.

It is thus possible, by measuring the distance between two maxima on the curve, to find the distance the water has travelled in a year. The minima can be treated similarly.

Fig. 2 shows the velocities which have been calculated in this way. The circles represent velocities calculated from the maxima, and the crosses those calculated from the minima. The difference between the two curves can be explained if the cold water which sinks in winter flows more quickly than the warmer water which sinks in summer. This might be the case owing to greater density of the cold water.

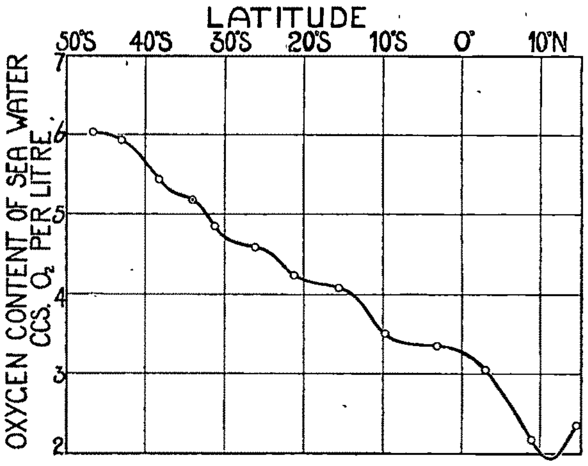

Fig. 1.—Variation of the oxygen content of the Antarctic Intermediate Water with latitude.

The conclusions reached are:

1. The stream of Antarctic Intermediate Water takes approximately five years to cover the 3300 miles between 40° S. and 15° N.
2. The northerly and principal component of its velocity increases from an average value of 1·2 miles per day in 40° S. to 2·5 miles per day in 7° S.
3. South of 20° S. there is a difference between the velocities of the water which sinks in winter and in summer.
4. The oxygen in the Antarctic Intermediate Water is used up between 40° S. and 10° N. at the rate of 1 c.c./litre in about 850 miles.

A similar method of investigation is being used to find the velocity of the North Atlantic Deep Current flowing southward at a depth of 2000–3000 metres.

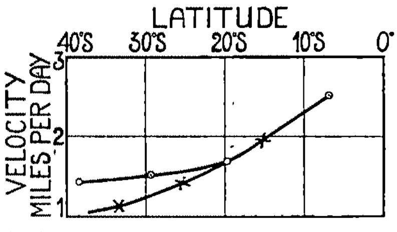

Fig. 2.—Variation in the velocity of the Antarctic Intermediate Current with latitude.

The curve of oxygen content is, however, affected by the influence of the Mid-Atlantic Ridge on the deep water movements, but a possible figure for the velocity of the deep current is 2·2 miles per day in 10° S.

This method of measuring current velocities in the Atlantic Ocean is described by Wattenberg[1] for the North Atlantic Deep Current, but no figures are given.

G. E. R. Deacon.

Subjective Interpretation of Loudspeaker Frequency Response Curves in terms of Loudness.

IN objective measurements of the overall response of sound reproducing systems, the need is continually felt of a method of interpreting them subjectively. We have found it possible, by utilising Kingsbury's scale of loudness and his measurements at different frequencies connecting the sensation level of a pure tone with its loudness,[1] to derive loudness-frequency characteristics. By way of example, in Fig. 1, is shown a typical measured acoustical response curve for a high quality loudspeaker. This type of curve can refer to the loudspeaker when supplied with constant current or when associated with its amplifier, or to the overall response characteristic corrected for different factors such as the change in the polar distribution of radiation with frequency.

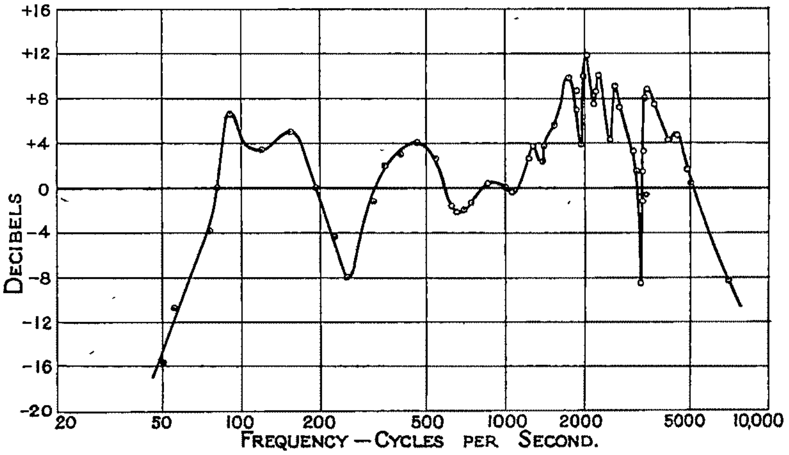

FIG. 1.—Typical acoustical response characteristic for a loudspeaker.

In Fig. 2 are shown the deduced loudness-frequency characteristics, corresponding to the objective curve in Fig. 1, for specified sound pressure levels at 1000 cycles per second (the frequency of zero level in Fig. 1), and these characteristics refer to the loudnesses of single pure tones when listened to in silent surroundings. The smooth chain curves passing through them refer to an ideal system in which the response is perfectly uniform at all frequencies. Departures of the actual loudness curves from these smooth curves give a measure of the frequency distortion of the apparatus in terms of loudness, and an observed variation in response in Fig. 1 is seen to cause a greater percentage change in loudness as the volume level of reproduction is decreased. Such curves as those shown in Fig. 2 are valuable as showing quantitatively how the apparent frequency range and tonal balance depend upon the absolute value of the sound pressure at the ear. The effect is analogous to the well-known change in tonal quality as one walks away from a band playing in the open air. The sound pressure at the ear is determined by either the distance from the source of sound or the overall characteristics of the electro-acoustical system. Solid models can be constructed from which the loudness may be read immediately at any frequency and sound pressure.

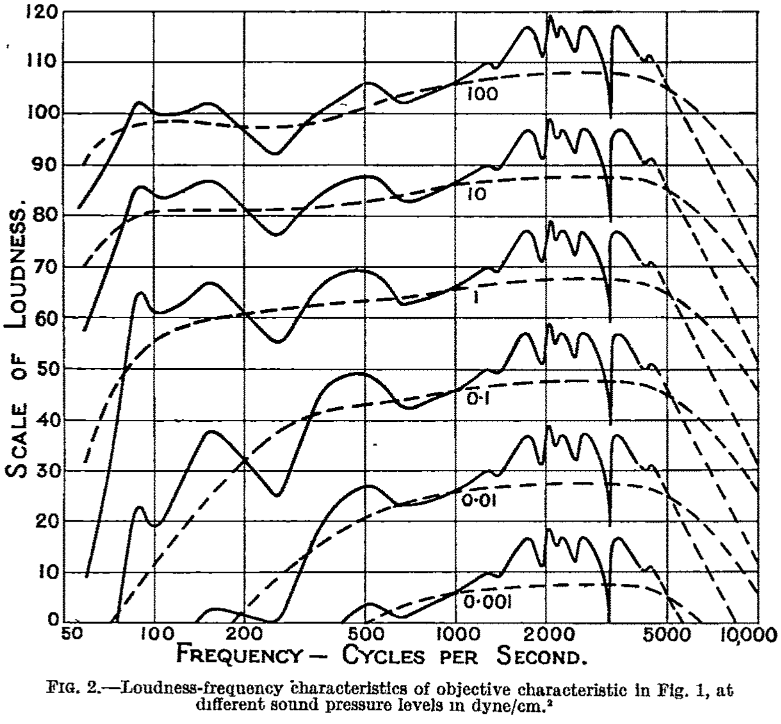

FIG. 2.—Loudness-frequency characteristics of objective characteristic in Fig. 1, at different sound pressure levels in dyne/cm.^2

It is hoped to discuss some cases of technical interest at a later date.

Classification for Bibliography of Science.

MR. BLISS[1] has proposed the thesis, with which he is so good as to couple my name, that classification should be applied methodically to scientific literature and that the study of classification should now become a first concern of national and international organisations.

I am very glad to see that Mr. Bliss recognises the necessity for tackling the overwhelming output of scientific and technological writings. But I am not quite satisfied with his presentment of my case. I hope I am not doing him an injustice, but Mr. Bliss appears to be more interested in the perfection of the classification used than in the indexing of the literature, or, he seems to think that a perfectly logical classification is necessary for the preparation of a subject catalogue. But those who are working for the production of a comprehensive index to published scientific and technical information are inclined to look upon the classification adopted as merely a means to an end, and to criticise its comprehensiveness and flexibility rather than its philosophical basis.

In our view, the task of indexing the scientific and technical papers published throughout the world needs the employment of an army of bibliographers, the co-ordination of whose labours depends upon the use of the same classification. In such a way the International Catalogue of Scientific Literature was organised. On account of the many bibliographies of all kinds now in course of publication, we believe that general agreement by a number of bibliographers and bibliographical undertakings to adopt a standard classification would go a long way towards the immediate realisation of an extensive index to recorded information. We recommend the Universal Decimal Classification as being the only code, at present available, which is sufficiently comprehensive and minutely subdivided for the purpose.

I am sorry to be obliged to point out some small errors in Mr. Bliss's letter. The original Dewey classification was adopted by the International Bibliographical Conference (as the basis of an international bibliographical classification) in 1895, before, and not after, the issue of the report of the Committee of the International Catalogue of Scientific Literature.[2] Moreover, there is a large section for Biochemistry, termed Physiologic Chemistry, under 612.015, which is mentioned in the index to Dewey's decimal classification. It need scarcely be said that the subject is fully developed in the Universal classification. Further, I do not understand Mr. Bliss's objection to my use of the name "Universal Decimal Classification", which is the description on the title-page.

Mr. Bliss alleges that this classification is undeniably disqualified as being illogical and unscientific, for the reason that Science in Class 5 is separated from Philosophy in Class 1 and placed subsequent to Social Science in Class 3, which is remote from History in Class 9; that Philology in Class 4 is dissevered from Literature in Class 8, and so all the literatures from their languages; and further, that Biology and Psychology are not treated as distinct fundamental sciences but misrelated and dispersed. I am not quite clear as to the implication of the last sentence, but, as we are admittedly considering only scientific literature, I scarcely think that Mr. Bliss can claim that "These few examples [outside science] . . . justify . . . [the] criticism that . . . [the system] is disqualified and inadaptible ".

In regard to Mr. Bliss's objection to the decimal notation, it may be said that, in practice, numbers are found to be quicker, and therefore cheaper, for filing than letters. It would be interesting to know how Mr. Bliss would classify a paper on "Relation entre les gradients du potential Newtonien sur un plan et son application à l'étude des anomalies gravifiques et magnétiques" according to his system.

Mr. Bliss goes on to say that he thinks that it would not pay to standardise an arbitrary classification for scientific bibliography, and proposes the co-operative development and standardisation of a basic classification and notation, consistent with accepted principles and with the organisation of science. No doubt librarians would be delighted to possess a classification which should be perfectly logical and consistent with accepted philosophical principles. But does Mr. Bliss really imagine that general agreement on the logical arrangement of even the main classes of knowledge could ever be attained? Every expert regards his subject as that in relation to which all others should be arranged, and no two experts would agree. Even if the best compromise were eventually accepted, the progress of discovery would render it obsolete in a day.

In the meantime, we have in the Universal Decimal Classification a bibliographical tool which has gradually been elaborated and improved by the collaboration of many hundreds of experts in the light of a quarter of a century of experience. Somewhat illogical in parts as it admittedly is, in practice, it proves to be adequate for the indexing of scientific and technical literature on the largest scale. Its use is extending day by day, and, with its aid, the 'subject index illusion' is being realised. S. C. Bradford.

The Velocity of Light.

In Nature of June 13, 1931, p. 892, Mr. Gheury de Bray brings forward two new possibilities for the explanation of the decrease of the velocity of light. As in my opinion both of these possibilities lead to difficulties, perhaps I may be permitted, in view of the importance of the subject, to offer some comments upon them.

The first possibility is in contradiction to the supposition on which at one time the elastic theory of the light of material ether was built up. I am thinking of the equation $c=\sqrt{N/\rho}$ (Fresnel, Neumann), where c stands for the velocity of light; N, rigidity; and ρ, density of the ether.

As regards the second possibility mentioned in the explanation, that is, the idea of the increase of the distance of the two points in the course of time, the matter is a little difficult, as Mr. Gheury de Bray has not explained it in detail or mathematically, and without a mathematical deduction one cannot clearly gather what he really means. For this reason, I may be permitted to add to the idea of Mr. Gheury de Bray as much as seems necessary in order to explain my calculations.

The velocity of light is determined by the equation $c=s/t$, whereby s is the distance which the light has travelled, and t the time which the light has taken to travel such distance. Let us say that s is the distance of these two 'stable' points (base of measurement), which we required fifty years ago to measure the velocity of light. Let us suppose that this distance is to-day essentially greater; but we cannot ascertain this, as the metre also is increased in the same proportion, so that we shall, in determining the basis, obtain the same measurable numbers as fifty years ago. If the velocity of light (if we can at all express ourselves to-day in previous measurements) has not changed essentially, and if not one unit of time has changed, then we shall to-day, in measuring the velocity of light according to the distance s, obtain another measurable number $c_1=s/t_1$, which is less than the previous one ($c_1<c$) as light now requires a longer time ($t_1>t$) to travel the materially greater distance s, which only by its measurable number appears equal to that of fifty years ago. The decrease of the velocity of light would in this case only be apparent.

It can be gathered from the hypothesis which I have outlined in the foregoing, that the right measure for the distance of the two points would be the time which the light needs to travel the same. If, for example, all distances have increased in the proportion $1:(1+\epsilon)$, then t_1 is $=t(1+\epsilon)$; if we designate $c_1=c-\Delta c$, whereby Δc is apparently a decrease in the velocity of light, then the equation $c_1=s/t_1$ becomes

$$c-\Delta c=s/t\,(1+\epsilon)=c\,(1-\epsilon),$$

and is therefore $\epsilon=\Delta c/c$. By substitution of the value $\Delta c = 2 \times 10^7$ cm./sec. and $c = 3 \times 10^{10}$ cm./sec., the result is $\epsilon = 6{\cdot}7 \times 10^{-4}$. This means that all distances in the last fifty years would have to be increased in the proportion of 1 : 1·00067.

One would have to enlarge in the same proportion the distance of the planets from the sun, and the reciprocal distance between double stars. Let us suppose that the masses of celestial bodies are not altered in space through this increase, and also that the constant of gravitation is not changed thereby with regard to former units of measure, then the period of revolution, T, of each planet and of each double star would have had to change in the last fifty years to T_1 according to the third law of Kepler:

$$T_1^2 : T^2 = 1{\cdot}00067^3 : 1^3,$$

and from this we can calculate that $T_1 - T = T/1000$. This, for example, means that the time which the earth takes to revolve around the sun would have been increased in the last fifty years by 1/3 day!

I must emphasise that, in spite of all these difficulties, the suggestion of the aforesaid hypothesis by Gheury de Bray has its scientific value. It is necessary that all possible explanations be brought forth, in order to illuminate this question from all sides, but it is also the task of science to find out, after a critical examination, which interpretation is the most probable.

I stated last year that the decrease in the velocity of light, if this exists, is not in contradiction with the theory of relativity, and that, therefore, one could interpret this eventual decrease in accordance with this theory, that is, with the changes in time of g_{hk}. The change in the velocity of light would in this case be real. If the expansion of the universe is the cause of the decrease in the velocity of light, then this would mean that this is an actual case of the so-called λ-effect of the general theory of relativity, as one should, according to de Sitter, consider the expansion of the universe as such an effect of this same theory.

The Bottle-Pipe Resonator.

IN the issue of NATURE of Aug. 30, 1924 (p. 309), Aldis gave a formula for a resonator consisting of a closed cylindrical pipe of large diameter (length L) connected to an open cylindrical pipe of smaller diameter (length l) which he termed a 'bottle-pipe', namely, $\tan(2\pi l/\lambda).\tan(2\pi L/\lambda) = S_a/S_D$ where S_a and S_D are the sectional areas of the smaller and larger pipes respectively and λ is the wave-length of the natural frequency. The accuracy of the formula was questioned in a later number.

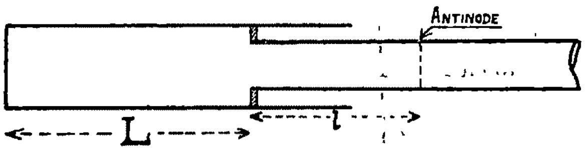

FIG. 1.

I have recently been experimenting on such a bottle-pipe resonator. To sound the resonator and eliminate the end-correction, I attached this resonator to the end of an open organ pipe, of which the diameter was equal to the diameter of the smaller portion of the resonator. The resonator was then adjusted until the system spoke at the original natural frequency of the pipe. The antinode at the end of the open organ pipe thus becomes an antinode of the open end of the bottle-pipe resonator, and the corresponding end-corrections of the pipe and the resonator are, therefore, eliminated (Fig. 1).

The method of blowing the pipe at the proper pressure and the determination of the position of the nodes in the pipe were as described in my papers in the *Phil. Mag.*, November 1929 and October 1930.

The experiment was repeated with varying lengths of the two sections (L and l) of the bottle-pipe resonator, and the results are shown on the accompanying curves (Fig. 2). The dotted curve gives the relation between the total length ($L + l$) of the resonator and the length L of the bottle section, for a frequency of 260 cycles per second. The full curve gives the relation between the two sections of the resonator; it is symmetrical about the axes, which is to be expected from the reciprocal nature of the formula.

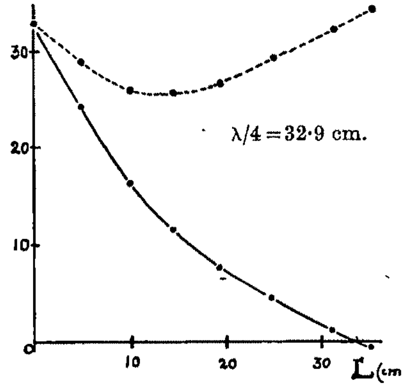

FIG. 2.

It will be seen that the ordinate of the dotted curve passes through a minimum value when the two sections of the resonator are of equal length, that is, $L = l$. In my case, these were found to be 12·9 cm., both practically and by calculation. Further, it will be seen that the relationship remains true even when the bottle section is indefinitely shortened.

I hope to publish shortly the full account of the experiments.

Absorption Spectra of the Ce^{+++} Ion in Solution.

THE experiments of J. Becquerel and W. J. de Haas [1] on the paramagnetic rotation of the plane of polarisation of light in a crystal of tysonite (which is a fluoride of cerium and lanthanum) has created an interest in the absorption spectra due to the Ce^{+++} ion. These authors, as a result of their measurements at low temperatures, and on the assumption that the dispersion produced in tysonite is due to the presence of a single absorption band, came to the conclusions that (i.) the rotation phenomena are due to the presence of the Ce^{+++} ion, and (ii.) the position of the absorption band is somewhere in the region of 2370 A.

Gibbs and White,[2] in their study of the relations between the doublets of stripped atoms in the different periods of the periodic table, found in the spark spectra of cerium a doublet with wave-lengths 2779·1 A. and 2457·6 A., which they attributed to Ce$^{\mathrm{iv}}$ corresponding to the transitions $6\,^2S_1 - 6\,^2P_{1,2}$ with $\Delta\nu(^2P_1 - {}^2P_2) = 4707$ cm.$^{-1}$. The nearness in the values of the calculated wave-length of the absorption band in tysonite and that of one of the lines of the doublet attributed to Ce^{+++}, made it appear worth while to investigate the absorption spectra of the Ce^{+++} ion in solution. For this purpose we prepared cerium chloride ($CeCl_3$) from chemically pure cerium nitrate. In solution it is known that the Cl^- ion shows absorption for wave-lengths $< 200m\mu$, and therefore the region where the absorption due to the Ce^{+++} ion was expected would not be masked by the presence of the Cl^- ion. As a result of our investigations, we found two regions of selective absorption, which appear fairly narrow in width and of measurable intensities at two different dilutions. In the following table their positions are given, with the dilutions at which they appear most distinct. The wave-lengths of the emission doublet attributed to Ce^{+++} ion is also given.

Dilution.	Absorption wave-length.	Emission wave-length.
1/40 mol.	2960 A.	2779 A.
1/1000 mol.	2550 A.	2457 A.
	$\Delta\nu = 5432$ cm.$^{-1}$	4707 cm.$^{-1}$

It appears that the agreement between the two sets of values are as good as can be expected under the given conditions. The absorption lines are shifted towards the longer wave-length side. From magnetic measurements made on cerium salts, both in the solid state and in solution, it is known that the Ce^{+++} ion is in the $4\,^2F_{\frac{5}{2}}$ state corresponding to the following electronic distribution :

$$\begin{matrix} 4f & 5s & 5p \\ 1 & 2 & 6 \end{matrix}$$

By light absorption the $4f$ electron is raised to the $5d$ level, giving rise to $5\,^2D_{\frac{3}{2},\frac{5}{2}}$ terms. The calculated relative intensities of the doublet lines due to the transitions $4\,^2F_{\frac{5}{2}} \rightarrow 5\,^2D_{\frac{3}{2},\frac{5}{2}}$ is 14 : 1.

The result of our observation is compatible with the predicted ratio of intensities, if it is assumed that the $^2D_{\frac{5}{2}}$ term represents the higher energy level. The shift of the absorption band towards the longer wave-length side can be explained as due to the work done on the radiating electron by the surrounding dipole water molecules, when it is shifted from the inner $4f$ orbit to the outer $5d$ one, on the periphery of the Ce^{+++} ion.

Band Spectrum of the Green Flame of Phosphorus.

I HAVE made several unsuccessful attempts within the last two years to obtain a satisfactory photograph of the band spectrum of the green flame obtained when hydrogen containing a little phosphorus vapour is burnt in the air. The difficulty has mainly been that photographic plates are very insensitive in the green and the flame is not easily maintained for long periods.

I have recently obtained a good photograph, giving an exposure of 100 hours, using a two prism glass spectrograph giving a dispersion of about 10 A. per mm. in the green. In the most intense bands there is considerable overlapping, but a fainter band at λ 5066 comes out clearly, and Fig. 1 is a reproduction of a register of the band made for me very kindly by Dr. Baker, of the Royal Observatory, Edinburgh. The appearance is very like that of an infra-red vibration-rotation spectrum, but might be an electronic band in which the moment of inertia of the molecule in the excited and unexcited condition is very nearly the same.

The separation of the bands is about 14·4 cm.$^{-1}$ on the blue side of the gap and 18 cm.$^{-1}$ on the red side. The frequency differences between the gaps in the strongest two pairs of bands are 1187 cm.$^{-1}$ and 1306 m.$^{-1}$, but these measurements are only rough at present and the analysis of the whole system has not yet been made. The moment of inertia calculated from the value 14·4 cm.$^{-1}$ is $3{\cdot}95 \times 10^{-40}$, which is not conclusive but suggests that the emitting molecule is more likely to be a hydride than the P_2 molecule.

Ultra-Violet Absorption Spectra of Cyanogen and the Cyanogen Halides.

WE have photographed the absorption spectra of cyanogen chloride, bromide, and iodide, and cyanogen itself in the gaseous state. The light source was a water-cooled quartz hydrogen tube consuming 0·5 amp. at 10,000 volts, from which the emission was perfectly continuous up to the short wave-length limit of the spectrograph (1840 A.).

Cyanogen chloride (pressure, 760 mm.) and cyanogen bromide (pressure, 76 mm.) showed continuous absorption, beginning about 2240 A. and 2540 A. respectively, and extending in each case to 1840 A. Cyanogen iodide at room temperature has a continuous absorption with long wave-length limit about 2150 A. At higher temperatures (100° - 125° C.) another region of continuous absorption appears with a maximum of 2500 A. and long wave-length limit at 3100 A.

The most probable mechanism for the photo-dissociation seems to be

$$CN.X + h\nu \rightarrow CN' + X$$

where CN′ has the excitation energy 41 kcal. in all cases except the far ultra-violet absorption of cyanogen iodide, where CN′ has 73 kcal. excitation energy. This leads to values 86, 71, and 51–59 kcal. for the heats of dissociation of cyanogen chloride, bromide, and iodide respectively into CN and halogen atom. These values are each about 10 kcal. greater than the mean values given by Eucken for the carbon-halogen linkages in aliphatic compounds.

The absorption spectrum of cyanogen is discontinuous. Between 2380 A. and 1860 A. there are about forty bands, shaded towards the red. Some of these show rotation structure. The bands do not converge before 1850 A. (154 kcal.); the heat of dissociation of $(CN)_2$ into 2CN must therefore be greater than 81 kcal., if the dissociation at the convergence limit leads to CN and CN′ (73 kcal.). The heat of dissociation calculated from thermochemical data is 66 kcal. The photo-dissociation may, however, produce vibrating CN molecules. This would account for the discrepancy. A full description of these absorption spectra will be published shortly.

The Critical Increment of the Adsorption of Hydrogen on Amorphous Carbon at 400° - 520° C.

The rates of adsorption of hydrogen on amorphous carbon have been measured for pressures ranging from 1 cm. to 10^{-3} cm. of mercury. Assuming that the rate of reaction is proportional to the pressure and to the surface covered, the rates will be given by the equation

$$-dp/dt = k(Ap + p^2)$$

where k is the velocity constant and A is a constant containing the area. This equation holds for the whole range of pressures and temperatures investigated, but A is not independent of temperature; it practically doubles as the temperature is increased from 400° to 520° C. The values of log k plotted against $1/T$ give a straight line, and from the slope a critical increment of 30,000 cal. is calculated.

If the reaction be written,

$$(1)\ 2C_s + H_2 = 2C - H,$$

and Mecke's values for the C - C, C - H, and H - H linkings be adopted, namely, 65, 90, and 101 kcal., the reaction is exothermic to the extent of 14 kcal., and if the carbon surface be activated, the heat of reaction will be larger. It is doubtful if the reaction actually occurs in this way, for the adsorbed gas is evolved as hydrogen on evacuating under a high vacuum at 800° - 900° C., whereas if the hydrogen had combined with the carbon, some methane would be expected. There is thus no evidence that the hydrogen has entered into chemical combination with the surface. It is possible, however, that the hydrogen molecules are dissociated into atoms by the process,

$$(2)\ 2C - + H_2 = 2C_s + 2H,$$

which is endothermic to the extent of 30–35 kcal., which corresponds with the observed critical increment. The result of the change is a deactivation of the surface with the production of adsorbed hydrogen atoms. On desorption, however, the surface returns to its original activity, so that if the above process occurs, it must be reversible.

The adsorption of hydrogen on carbon at 450° C. resembles that found previously for the adsorption of hydrogen and carbon monoxide on $ZnO - Cr_2O_3$ at room temperature,[1] and for the adsorption of hydrogen on manganese dioxide at 400° C.[2] It is unlike that of oxygen on carbon at room temperatures, for in this case the oxygen can only be removed from the surface in combination with carbon, and it is different from that of hydrogen and carbon monoxide on $ZnO - Cr_2O_3$ at 100° C., for these gases remove oxygen atoms from the surface on desorption. The adsorption of hydrogen on carbon appears to be of a type intermediate between van der Waals' adsorption and true chemisorption.

The main difficulty in the acceptance of equation (2) lies in the fact that carbon monoxide also gives rise to the intermediate type on oxide catalysts, where dissociation into atoms is not possible.

Intensity of Raman Scattering in Gases.

Using the apparatus described in earlier notes in Nature, it has been found possible to estimate by photographic photometry the intensities of the Raman lines given by various simple gases and to make a quantitative test of the theory put forward by Manneback.[1] The results, on the whole, seem to be favourable to the theory. The intensities of the rotational Raman lines representing the $0 \rightarrow 1$, $1 \rightarrow 3$, $2 \rightarrow 4$, and $3 \rightarrow 5$ quantum transitions in hydrogen gas are respectively in the ratio 1 : 3 : 0·4 : 0·2, Manneback's values being 1 : 2·8 : 0·35 : 0·19. His theory further enables us to express the absolute intensities of these lines as fractions of the undisplaced Rayleigh lines if the optical anisotropy of the molecule is known. This may be computed from the observed depolarisation of the Rayleigh scattering. In the case of hydrogen, the calculated intensity of the $0 \rightarrow 2$ rotational line, the first of the above series, comes out as $3{\cdot}5 \times 10^{-3}$, the observed value being 2×10^{-3}.

Manneback's expressions further show that while the Rayleigh scattering depends on the optical polarisability and anisotropy of the molecules, the vibrational Raman lines are connected with the variation of these quantities with varying nuclear distance. We have at present no experimental knowledge of the latter quantities, but following a method due to Ramanathan[2] it is possible to estimate them theoretically and thus evaluate Manneback's formulæ numerically. In this way it is found that the intensity of the strongest line in the Q branch of H_2 ($0 \rightarrow 1$ vib. $1 \rightarrow 1$ rot.) when expressed as a fraction of the Rayleigh line should be $1{\cdot}63 \times 10^{-3}$, while the observed value is $1{\cdot}5 \times 10^{-3}$. A qualitative agreement is also found with oxygen (O_2) and nitrogen (N_2). It may be noted that the existence of nearly unpolarised rotational Raman scattering with appreciable intensity necessitates a revision of the hitherto accepted values of the depolarisation of Rayleigh scattering, and this has been taken into account in the above computations.

Anomalous X-ray Diffraction Intensities.

The general explanation of the observations previously described under the above heading[1] probably follows, as stated there, from the well-known Laue equations connecting line-breadth with the size of a crystallite measured in a direction a_1. I have recently become aware of a paper by R. Brill,[2] in which this aspect of Laue's work first appears to have been demonstrated quantitatively, and I would like to add this to my former note in order to direct attention to that paper.

Research Items.

Hippopotamus Figures from Ancient Egypt.—Mr. W. M. Crompton describes two hitherto unpublished hippopotamus glazed figures in *Ancient Egypt*, 1931, pt. 1. The first was found by the expedition of the School of Archæology in Egypt to the Fayum in 1913–14, in a shaft-grave of the twelfth dynasty near Haregeh. The figure lies with the head turned to the right in a natural pose. It was originally covered with blue glaze, and decorated with designs in black outline, representing the fauna and flora of the marshes frequented by the animal, which was seldom seen except in glimpses through such a foreground. Recently Dr. L. Keimer has published a study of thirty-six decorated hippopotami. On twenty-six examples, including that from Haregeh, decorative motives appear as follows: the flowers of *Nymphaea sp.* appear in all but one, which is entirely decorated with pondweed. The leaves and buds almost invariably appear. Shining pondweed (*Potamogeton lucens* Linn.) appears on five. The papyrus is shown three times only. Rosettes are usual, but not invariable. Birds appear six times; butterflies three, or possibly four times; and a bee once. In one instance there is a frog half emerging from a lotus flower. Decorative bands are found four times and a network once. The representation on an animal figure of objects with which it was supposed to be surrounded was not, until recently, known to occur before the Middle Kingdom. It has now been carried back to the Middle Predynastic period; for Mr. Brunton has found at Badari a fragment of a pottery hippopotamus on which is the design of a ship and men with harpoons, evidently meant as surrounding the animal with intent to destroy it.

Evolution in the Chelonia.—P. E. P. Deraniyagala, in the *Proceedings of the Zoological Society*, Part 4, 1930, gives a reasoned account of his views on testudinate evolution and upholds the thesis that the Athecæ, the leathery turtles, are the more primitive type in the structure of the carapace, as well as in many other features. He points out that the current view that the Athecæ have lost the endoskeletal expansion of the ribs, and consequently the carapace plates, is not necessarily correct, being due to a wrong bias from palæontology. The rarity of Athecæ in any except recent deposits is not due to their recent evolution, but can be explained by the fact that on death their skeletons fall apart and are not preserved as are the well-knit bodies of the Thecophora. As a matter of fact, the earliest known of Chelonian remains, *Psephoderma alpina*, from the Triassic, is claimed as Athecan. The author considers that the original Chelonia were marsh dwellers and at first had a dermal covering with an external layer of ossified scales and a non-retractile neck. It was at this stage that the Athecæ took permanently to marine life, retained the primitive scaling, and never acquired the retractile neck.

Sex-change in the Oyster.—Prof. J. H. Orton and C. Amirthalingam (*Jour. Mar. Biol. Assoc.*, 17, No. 2, 1931) record observations on sex-change in the European oyster (*Ostrea edulis*). Oysters in which a batch of eggs has been passed into the mantle cavity normally immediately begin to develop spermatozoa, and this process is so rapid that in a few hours after extrusion of the eggs small clumps of spermatocytes can be recognised in the gonad. Within about fourteen hours from the extrusion of ova, relatively large clumps of spermatocytes are recognisable in the gonad, and within about forty-five hours the gonadial tubes become filled with maturing sperm. About eight and a half days after the extrusion of ova, when the larvæ which the oyster is carrying have become fully developed veligers ready to be liberated, sperm development may have proceeded so far that the gonadial ducts become filled with ripe sperm-morulæ. After the larvæ have been liberated, sperm production continues, but about a month after extrusion of the ova begins to wane and in another month has usually ceased if the egg-spawning has occurred in early or mid-summer. The gonad passes into a quiescent condition, and a period of fattening, that is, the accumulation of reserves, usually follows. If egg-spawning occurs in late summer, the sperm afterwards developed may be retained over the winter period. Instructions are given for making the microscopic preparations of the gonad, and illustrations are added to represent the condition as seen in fresh preparations and in sections.

Anterior Abdominal Vein in the Toad.—We have received a communication from Prof. Ekendranath Ghosh and Birendrakumar Mitra, of the Medical College, Calcutta, stating that, while examining about fifty dissected toads (*Bufo melanostictus* Schneider) in a medical examination conducted by Prof. Ghosh, they found a normal-sized anterior abdominal vein, arising in the usual way and ending in the left subclavian vein. The vein had no connexion whatever with the liver or hepatic portal vein. The animal was an adult male. This is the second abnormality of its kind to be recorded for this species. The previous example, where the anterior abdominal vein opened on the right anteriorly, was reported by Bhaduri (*Jour. Dep. Sci.* Calcutta, p. 1, 1929).

A Hypothesis of 'Sub-genes'.—Numerous papers have been published on the inheritance of bristles in *Drosophila*. A group of gene mutations which reduce the bristles in different parts of the body has been studied. These genes are shown by their linkage relations to lie at the scute locus of the *X*-chromosome. To account for these phenomena, Serebrovsky and others have elaborated a hypothesis of 'sub-genes' arranged in linear order, each concerned with the development of one or a few bristles on the fly. The various mutations which scute undergoes are then each supposed to represent a change in a different block of sub-genes. Sturtevant and Schultz (*Proc. Nat. Acad. Sci.*, vol. 17, No. 5) have constructed a similar series of bristle-effects from their experiments, but they interpret it in a different way. Hairless is another gene (in chromosome III.) which removes the bristles in a different pattern from that of the scute series, and achete also inhibits bristle development. By experiments involving these series of forms, it is shown that scute 1 and achete act on bristles throughout the length of the series and not on particular bristles alone. Thus since each 'sub-gene' is affecting many or all the bristles of the fly, though in different degrees in different parts of the body, the basis of the sub-gene hypothesis is undermined and the usual conception of the interaction of genes in controlling development is adhered to instead. The pattern of bristle-effects is explained rather as due to the paths and rates of diffusion of certain substances during development.

Pivots and Jewels.—H.M. Stationery Office has issued at the price of 4*s*. a well illustrated 4to pamphlet of 55 pages describing the work done at the National Physical Laboratory, by Mr. V. Stott, on the conditions favouring smooth running and long life of the pivots and jewels which play so important a part in watches and scientific instruments of all kinds. Mr. Stott has investigated the most suitable shape and hardness of a pivot to carry a given load, and has measured the friction between the pivot and jewel and the torque due to it. He finds that during the rotation of the pivot rust is formed, and that this rust is the main cause of the increase of friction during wear. Lubrication does not diminish the friction between the pivot and jewel, but its presence considerably increases the life of the bearing. The relation between the direction of the hole in the sapphire or diamond and its crystalline axis has an influence on the wear of the bearing.

Flame Propagation in an Electric Field.—Prof. W. A. Bone, R. P. Frazer, and W. H. Wheeler have contributed a paper to the July number of the *Proceedings of the Royal Society* on the effects of an electric field upon the propagation of flame through a dry mixture of carbonic oxide and oxygen. The gas was dried by prolonged contact with phosphoric anhydride, the combustion started by a spark, and the progress of the flame recorded photographically. An electric field was applied between electrodes in the gas, and control experiments made in the absence of a field in otherwise similar apparatus. Their results show a definite effect of the sign of the pole on the flame; near the negative pole conditions are much more favourable to the continuance and propagation of the flame; and near the positive pole rather less favourable than in the field-free control experiments. There appear to be two distinct conditions in which the field has an effect: first, when the flame is being propagated through a dry medium in which the field is maintained, and secondly, when the flame fronts have nearly reached the poles and the field breaks down. In the first instance, there is a general drift of the medium towards the negative pole and also a sort of initial wave of positive ions in the same direction; and in the second, combustion is accelerated by the highly ionised condition of the medium. The paper is illustrated by some beautiful photographs of the moving flames.

Structure of XO_3 Groups in Crystals.—A paper by W. H. Zachariasen in the June number of the *Journal of the American Chemical Society* gives the general results concerning the structure of groups XO_3 in crystals, as determined by X-ray analysis. The groups are found to be of two kinds: (1) co-planar groups; BO_3''', CO_3'', and NO_3'; (2) pyramidal groups; SO_3'', ClO_3', AsO_3''', BrO_3', SbO_3'''. In the following table *a* denotes the oxygen to oxygen distance, *r* the cation to oxygen distance, and *h* the displacement of the cation from the plane of the oxygens, all in angstroms.

	BO_3	CO_3	NO_3	SO_3	ClO_3	AsO_3	BrO_3	SbO_3
a	2·35	2·13	2·14	2·24	2·38	3·28	2·76	3·62
r	1·35	1·23	1·23	1·39	1·48	2·01	1·68	2·22
h	..	..	..	0·51	0·49	0·67	0·56	0·75

The groups XO_3 are co-planar if the number of valency electrons in the group is 3×8, whilst a pyramidal arrangement seems to be connected with $3 \times 8 + 2$ valency electrons. An explanation of the formation of the asymmetrical groups in terms of ions and their polarisibility is given in the paper, and the values of *a* and *h* are shown to be related by the expression $12h = a\sqrt{6}$, which suggests a simple picture of the pyramidal groups as tetrahedral groups with three corners occupied by oxygen ions, the centre by the cation core, and the fourth corner by two displaced electrons or an equivalent concentration of electron density.

Astronomical Topics.

Nagata's Comet.—*Science News Letter*, dated Aug. 1 (Science Service, Washington, D.C.), gives information about the discovery of this comet: Mr. Masani Nagata is a native of Japan engaged on fruit-growing near Brawley, California; he possesses a 3-inch telescope, and in the course of observing Neptune on the evening of July 15 (July 16·2 U.T.) he swept up a nebulous object near it; the next night it had moved a degree to the north-east; he sent the news to Mt. Wilson, where Mr. Moore confirmed the discovery. There was a tail 4° long on July 18; the magnitude of the comet was given as 7 on July 23 and 9 on July 25, but it was probably really brighter, as twilight and atmospheric absorption would weaken its light more than that of the stars.

The following positions (for 1931·0) are from Harvard Cards 161–164:

Date.	R.A.	N. Decl.	Place.
July 18, 1792 U.T.	$10^h\ 40^m\ 44{\cdot}7^s$	9° 50′ 57″	Mt. Wilson
19, 1861	10 45 6·0	9 54 46	,,
20, 1795	10 49 22·3	9 58 12	,,
22, 2004	10 57 56·3	10 4 27	,,
23, 1157	11 1 46·1	10 6 50	Yerkes
25, 1933	11 10 20·8	10 11 22	Lick

The following ephemeris for 0^h U.T. is from *U.A.I. Circ.* 329:

	R.A.	N. Decl.
Aug. 19	$12^h\ 42{\cdot}5^m$	9° 52′
23	12 55·5	9 39
27	13 8·1	9 25
31	13 20·4	9 10
Sept. 4	13 32·4	8 54
8	13 44·1	8 37

The comet is receding from both sun and earth, so the brightness diminishes rapidly. The elements of the orbit show some resemblance to those of the comet of 1804; but this is probably not close enough to make identity possible; the inclination of Nagata's comet is about 14° smaller than that of the other.

Accuracy of the Heliometer.—Prof. de Sitter's George Darwin Lecture is printed in the May number of *Mon. Not. Roy. Ast. Soc.* In the course of it, he discusses the relative accuracy of heliometer measures and of those made on photographic plates. His decision is definitely in favour of the heliometer: he says, "the weight derived from an equal time of observing is for the heliometer more than four times that from one plate". One of the advantages of the heliometer is that the images of the two bodies are brought so close together that the eye can be concentrated on both of them at once. Prof. Schlesinger has shown that oscillations due to our atmosphere are alike for a region of considerable size, so that they do not affect the relative positions of the two bodies. He thinks that a heliometer of focal length 5–7 metres, with a power of 750, showing the satellites of Jupiter as discs, would help to settle a few questions, relating to their motions, that still remain uncertain. Most observers appear to consider the heliometer as obsolete; the Cape is the only observatory where it is extensively used: possibly Prof. de Sitter's words may encourage its reinstatement. It will be remembered that the first reliable star parallax was obtained by Bessel with a heliometer.

Royal Society of Canada.

Annual Meeting in Toronto.

On May 20–22 the Royal Society of Canada met at the University of Toronto. During the evening of May 20 Dr. Charles Camsell, Deputy Minister of Mines, gave his presidential address, entitled "Canada's Position in the Mineral Situation of the British Empire". Dr. Camsell, while emphasising the fact that no nation is independent of others in the matter of mineral supply, pointed out that, mainly owing to the diversity and amount of Canada's mineral production, the British Empire approaches much more nearly to a self-supporting basis than any other political unit. At the same meeting, the Flavelle medal was awarded to Dr. F. G. Banting, for his pioneer research on insulin; the Lorne Pierce medal to Adjutor Rivard, for outstanding contributions to literature, and the Tyrrel medal to Dr. Lawrence J. Burpee, for valuable historical work. The customary popular lecture was this year given by Dr. J. S. Plaskett, Director of the Victoria Observatory, on the "Structure and Motions of the Galaxy". A novel feature of the meeting was a series of radio talks by the presidents of the various sections, which were broadcast over the Dominion.

Section III. (chemical, mathematical, and physical sciences) divided into sub-sections to hear its 117 papers. The sectional presidential address was delivered by Prof. F. B. Allan on the position of organic chemistry to-day. A large number of papers were presented on spectroscopy by Prof. J. C. McLennan and his colleagues, Dr. J. S. Foster and his co-workers, Dr. W. H. Martin, and others. Among these papers, mention may be made of a paper by Prof. McLennan and R. Turnbull on "The Absorption Band of Xenon at λ 1469". The results indicate that by the absorption of ultra-violet light of very short wave-length, xenon atoms become enabled to enter a short-lived state of excitation during which they can and may combine with other xenon atoms. They have been able to separate the widening of the absorption band due to the number of molecules from the widening due to the pure pressure effect, for which a theory has been developed and extended by Franck in his lecture at Bristol last summer.

Other papers by Prof. McLennan and Messrs. E. J. Allin, A. B. McLay, M. F. Crawford, L. B. Leppard, A. M. Crookes, and K. E. Hall gave interesting accounts of research work on the properties of atomic nuclei—more particularly the nuclear spins. Further results on the height of the polar auroræ in northern Ontario were presented in a paper by Prof. McLennan, H. Wynne-Edwards, and H. J. Ireton.

Of the papers presented on the Stark effect, the most interesting was on "The Stark Effect in Hα", by D. R. McCrea. Asymmetry in the relative intensities of the components was found in pure hydrogen, which could not be accounted for by the known theoretical probabilities of the transitions. The addition of a small amount of the rare gases causes the intensities to become symmetrical.

In a series of experimental papers on low-temperature work at the cryogenic laboratories of Prof. McLennan, a number of interesting results were reported by Messrs. Wilhelm, Allen, and H. D. Smith. Among these, mention may be made of "The Electrical Conductivity of Ruthenium, Ruthenium Carbide, and Tungsten Carbide", in which the presence of a small amount of W_2C accounted for superconductivity results. Theoretical papers on the superconducting state were given by C. D. Niven, G. C. Laurence, and Prof. L. V. King. Dr. King's paper was perhaps the most outstanding paper of Section III. By assuming that the ion at the space-lattice be polarisable, so that the internal field acting on the free electrons is appreciably different from the measured applied field, he showed that the Wiedemann-Franz ratio depends on the specific inductive capacity of the space-lattice, the variation with temperature of which is given by Debye's formula. A satisfactory explanation is thus afforded of the variation of resistance with temperature. In particular, when the ions have permanent electric moments, the space-lattice may become permanently polarised when the temperature falls below a certain critical value, and superconductivity results. The agreement between theory and the experimental results of Lees and others was satisfactory.

Prof. A. N. Shaw gave new experimental data correlating thermo-electric force with temperature gradients, and Prof. J. Satterly spoke on the surface tension and viscosity effects on a draining plate. Dr. R. W. Boyle presented several papers by his colleagues of the National Physical Laboratory on ultra-sonics and allied subjects. Prof. J. A. Gray gave the results of further experiments on the scattering of X-rays at small angles and on the scattering of β-rays. He also read a short paper on the absorption of γ-rays.

Several papers on geophysics were presented. Prof. A. S. Eve gave the theory of a new method of finding the vertical depth of a buried magnetic dike, which was followed by an experimental paper on the same subject by Prof. D. A. Keys. Prof. L. Gilchrist presented the results of field work, comparing the single and his multiple electrode variation of the single-probe method of geophysical prospecting, and indicating the desirability of the latter arrangement over the region investigated. The results of a torsion balance survey in eastern Canada over pyrite and chromite deposits were read in a paper by A. H. Miller.

In the sub-section of mathematics and astronomy, which met jointly with the members of the Royal Astronomical Society of Canada, papers on astrophysics were read by Dr. J. S. Plaskett, Prof. C. A. Chant, Meldrum Stewart, W. E. Harper, Miss A. V. Douglas, and others. An interesting feature of the joint meeting was an account of the new David Dunlap Memorial Observatory and telescope which have been given to the University of Toronto. The new telescope, which is of the reflecting type, will be the largest in Canada, and the observatory will be under the direction of the Department of Astrophysics of the University.

Papers in pure mathematics were presented by Prof. S. Beatty, Prof. J. L. Synge, Prof. L. L. Dines, Prof. N. R. Wilson, Prof. DeLury, and their colleagues. Among these may be mentioned "The Derivatives of an Algebraic Function", by Dr. Beatty; "Constructing Basis for an Algebraic Number Field", by Dr. Wilson; "On Sets of Functions Orthogonal to a Positive Function", by Dr. Dines.

A large number of papers were presented in the chemistry sub-section by Profs. Lash Miller, O. Maass, H. Hibbert, and R. H. Clarke, and their associates. Prof. M. C. Boswell and W. H. Hutcheon spoke on an apparatus for studying the conditions influencing the yield of methyl chloride in the action of chlorine on methane, and Prof. J. B. Ferguson presented a paper on the co-existent vapour and liquid phases in the system, normal hexane-methyl alcohol at 45° C.

A demonstration of the new optical meteorograph was given by Mr. J. Patterson, secretary of Section III., by which the temperatures and pressures may be indicated in the upper atmosphere at night by means of electric light flashes. Prof. A. Norman Shaw was elected president of the Section for the coming year.

In Section IV. (geological and mineralogical sciences) thirty-one papers were presented. The meetings of the Section opened with the address of the president, Dr. E. M. Kindle, on "A New Viewpoint on Palæontology", in which he explained the preparation of a printed card index illustrating and describing type fossils. The attention of the Section was mainly occupied with a symposium on batholiths, H. C. Horwood, J. S. DeLury, T. T. Quirke, E. L. Bruce, J. A. Dresser, S. J. Schofield, W. T. Wright, and D. R. Derry contributing.

Papers on the late glacial history of the Great Plains were read by W. A. Johnston and D. A. Nichols, and E. S. Moore described an old glacial valley on Michipicoten River, northern Ontario. Papers also dealt with the following subjects: "The Devonian and Siberian Rocks of Gaspe and Northern New Brunswick, and Topographic Deflections in the Gaspe Peninsula" (F. J. Alcock); "A New Lower Jurassic Fauna in the Rocky Mountains" (P. S. Warren); and "The Re-crystallisation of Gypsum, illustrated by Microphotos on Cinema Films" (G. M. Thomson). Other papers were read by titles and will appear in the transactions. Mr. W. A. Johnston was elected president of the Section for the coming year.

In Section V. (biological sciences) sixty-six papers were presented. The presidential address by Dr. Jas. Miller was on the subject of "The Glomerulus of the Kidney: An Anatomical and Pathological Study". As an historical review and a summary of recent work, the address, printed in the proceedings, will be useful. Botanical papers came first. Frère Marie-Victorin presented a series of papers by himself and co-workers, extending their important phytogeographical and taxonomic studies of the flora of the north-eastern part of Canada. Various new relic species were described.

F. E. Lloyd classified *Utricularia* species according to their trap mechanism. G. W. Scarth presented a paper by himself and A. B. Brown on the "Effects of Temperature on Stomata"; A. H. R. Buller showed that a yeast *Sporobolomyces* discharges aerial spores in the same manner as *Basidiomycetes*, and should probably be classed among the latter. He also described the phenomenon of puffing in the *Discomycetes*. Papers presented by W. P. Thompson were taken as read in his absence.

Anatomical, biochemical, pathological, and physiological topics were dealt with by the majority of the papers in this Section. Mention may be made of the following: Pierre Masson, "Sur les propriétés organogéniques des cellules de Schwann". J. G. Fitzgerald and co-workers were responsible for some seventeen papers on toxins, sera, etc. Among the more notable were: the account by N. E. McKinnon and Wm. Knowles of "A Concentrated Anti-Vaccinal Serum" which may prove to be of value; that by C. H. Best, H. C. Foster, and L. Irving on "The Fate of the Sugar which disappears under the Action of Insulin" (confirming and extending the work of Best, Hoet, Marks, and Dale); and that by A. F. Charles and D. A. Scott on "Acetylation of Crystalline Insulin". Hardolph Wasteneys presented, among others, an interesting paper by H. D. Jenner and H. D. Kay on "The Place of Mg in the Phosphatase System", also one by A. A. Fletcher and Florence Hargreaves on "The Colon Condition in Rats with Vitamin B Deficiency", and one with B. F. Crocker, entitled "A Note on the Equilibrium of Peptic Synthesis".

Several papers were presented by V. J. Harding, of which one by T. F. Nicholson on "The Effect of Large Amounts of Urea on the Acid-Base Equilibrium of the Dog" raised the unanswered question of whether urea can function as a base; and another by Harding and D. E. Selby described how yeast (which ordinarily will not hydrolyse galactose) can be trained to do so in three generations, and can be used accordingly in urine analyses.

Among the more significant of the papers presented by Dr. J. B. Collip was one by J. W. Allardyce and L. I. Pugsley on "A Comparison of the Effect of Vitamin D and the Parathyroid Hormone on the Calcium and Phosphorus of Serum and Urine". Dr. Collip summarised in another contribution the physiological and chemical properties of the placental hormones. B. P. Babkin, in a paper on "The Innervation of the Salivary Glands", described the different effect of parasympathetic and sympathetic nerves on these glands. Jas. Miller, F. R. Miller, and V. E. Henderson also presented papers.

On zoological topics only a few papers were presented, namely, one by C. McLean Fraser on the ecology of the cockle; two by E. Home Craigie (presented by B. A. Bensley) on the cerebral anatomy of the humming bird and of the wild Norway rat v. albino, respectively; and one by A. Willey, entitled "*Glossobalanus Berkleii*, a New Enteropneust from the West Coast". Dr. J. B. Collip was elected president of the Section.

The president of the Society for the ensuing year is Sir Robert Falconer, Principal of Toronto University, and the vice-president, Prof. F. E. Lloyd of McGill. It is hoped that the 1932 meeting will take place in Vancouver, but no definite arrangement has yet been made.

Conference of Empire Survey Officers, 1931.

THE second conference of Empire Survey Officers, convened by the Secretary of State for the Colonies, was held on July 8–28, and, as a result of a decision taken at the first Conference in 1928, was devoted mainly to the subject of cadastral and property surveys and land registration. At the same time, opportunities were taken for giving attention to other branches of survey.

The meetings were held generally at the Science Museum, placed at the disposal of the Conference by Sir Henry Lyons, representing the Board of Education; but meetings were held also at the War Office, Surveyors' Institution, University of Cambridge, Admiralty, the Thames (Port of London Authority), Nautical Almanac Office, Royal Observatory, Southampton (Ordnance Survey), Liverpool Observatory and Docks, York, and Hull. At the last port delegates were permitted by the Admiralty to observe hydrographical methods on two of H.M. surveying ships operating in the North Sea.

Of the Dominions, Canada, New Zealand, and Newfoundland were unfortunately unable to send delegates, and of the Colonies only fourteen were represented, the world-wide depression being mainly responsible. In practically all cases, delegates were either survey officers at home on periodic leave or for other reasons.

The pressing need for extensive revision of the

Ordnance large-scale maps of Great Britain was brought to notice by Sir Charles Close, sheets in some cases being forty years out of date. Methods of map reproduction at home and in the tropics were discussed at the Ordnance Survey, Southampton, where Brigadier H. St. J. L. Winterbotham, the initiator and president of the Conference, and Major Clough, gave a description of the latest methods and processes of map-making. Triangulation was discussed by Dr. de Graaff Hunter and Capt. Calder Wood; traverses by Mr. J. Clendinning; gravimetry and the training of European surveyors were treated at Cambridge by Sir G. P. Lenox-Conyngham, Col. Craster, Prof. F. Debenham, and others; while Sir John Flett gave a remarkably lucid lecture on geophysical surveying, and Drs. Jeffreys and Hunter dealt with the relations between geophysics and geodesy. Air survey was brought forward by Capt. M. Hotine, air photography by Flight-Lieut. J. Bussey, aeronautical maps by Squadron Leader P. H. Mackworth, and air survey as applied to cadastral mapping in India by Col. R. H. Phillimore; a paper on the airman-surveyor by Mr. P. E. L. Gethin provoked a lively discussion. Admiral H. P. Douglas, to whom the success of the Conference was due in no small measure, described hydrographical methods. A summary presentation of the present knowledge of tides in British waters was given by Prof. J. Proudman, following an admirable description of tidal instruments by Prof. A. T. Doodson; Comdr. E. C. Shankland lectured on the hydrology of the Thames estuary. Optical distance measurement was dealt with by Major R. L. Brown, and the possible improvement of the barometer was not ignored. Sir Henry Lyons described early methods of survey in Egypt and the Roman Empire. The Astronomer-Royal gave the results of the most recent experience on the reception of *W/T* signals, and Dr. L. J. Comrie gave a lecture on the *Nautical Almanac* and mechanical computation.

It will be seen that much ground was covered outside the main work of the Conference. Within this sphere there was an eloquent address from Sir John Stewart-Wallace on land registration in Britain. Papers on land survey were sent by Mr. F. H. Peters, Surveyor-General of Dominion Lands, Canada, by Mr. A. H. G. Dawson, Surveyor-General of Ceylon, and by Mr. W. F. N. Bridges for the Surveyor-General of Malaya, the latter being a complete account of the survey and registration in that Colony. Mr. Maxwell Edwards, Surveyor-General of the Transvaal, and Mr. W. G. Fairweather of Northern Rhodesia read papers on property surveys and registration in their respective spheres. Lieut.-Col. C. H. Ley sent a paper describing the somewhat difficult cadastral structure of Palestine; another came from Mr. C. O. Gilbert, the Director of Surveys in Kenya. Col. M. O'C. Tandy annotated a paper by Cols. Campbell and Gwynn on rectangulation surveys in India, which bear some relation to the system in the Prairie Provinces of Canada; the discussion was continued by Colonel MacLeod, Chief of the Geographical Section of the General Staff, whose organising ability contributed greatly to the success of the meetings, at which he often took the chair in the absence of the president. It is not possible to summarise all the work done by willing hands in the field of land survey, but it may be said that there were few of the difficulties in the Empire which were not ventilated. A most instructive exhibit of cadastral maps was arranged at the Science Museum by the spontaneous labours of Sir E. M. Dowson; this was by no means limited to the Empire, since France, Italy, Switzerland, and Egypt made generous contributions, often involving a considerable amount of work.

Other subjects discussed were topography, the training of native surveyors, the *Empire Survey Review*, the Field Survey Association, and the position of the licensed surveyor in Canada, Kenya, Trinidad, etc.

These first two conferences have owed their success largely to the efforts of Sir Cecil Bottomley and to Mr. E. B. Bowyer, chairman and joint secretary of the Colonial Survey Committee. The proceedings will be published by H.M. Stationery Office early next year. It was decided to recommend the convening of a third Conference in 1934.

Coloured Glass as a Deterrent to House Flies.

AN interesting series of tests with the object of finding whether rooms glazed with 'Calorex' are likely, by virtue of the special properties of the glass, to be freer from insects than rooms glazed with ordinary glass has recently been carried out at the Imperial College of Science and Technology under the supervision of Prof. J. W. Munro, on behalf of Messrs. Chance Brothers and Co., Ltd.

Calorex glass is of a pale greenish-blue tint, and is designed to afford protection from excessive solar radiation by strongly absorbing infra-red radiation whilst transmitting in a useful degree the radiation within the visible spectrum. The present experiments, which have been conducted with several types of insect, but mainly with flies, bees, and wasps, confirm and amplify observations made at the Building Research Station at Garston, Herts, and described by Mr. H. E. Beckett in NATURE.[1]

House flies (*Musca domestica*) exposed to sunlight in a box, one half of which was glazed with Calorex and the other with ordinary glass, showed a marked preference for the ordinary glass, the ratio of the numbers of insects in the two halves, averaged over several experiments, being about 9 : 4. These results were verified by other tests in which the insects were not enclosed within the box but were attracted to it by a suitable bait. Wasps and bees were found to behave in the same way as flies.

Much of the preference shown is ascribed to the inequality of temperatures beneath the two kinds of glass, the disparity in insect population being greatest when the maximum temperature differences were observed. Confirmatory evidence of a positive effect with temperature differences maintained by agencies other than radiation is not, however, chronicled.

That an effect can definitely be ascribed to the colour of the light which has passed through Calorex was demonstrated by an experiment in which bees were enclosed in a glass cylinder, one end of which was closed with Calorex and the other with ordinary glass. By interchanging the glasses an immediate reaction was obtained, the bees moving to the end covered with ordinary glass.

The effect of coloured light does not seem to be peculiar to blue light. Messrs. Pilkington Brothers, Ltd., from experiments conducted last year, have stated[2] that the house fly prefers white light to coloured light, and that red and yellow are the best deterrents, being considerably more effective than blue and green. On the other hand, it has been stated[3] that blue glass is completely effective.

The most extensive use of coloured glass for this purpose at present seems to be in meat stores. In such buildings yellow glass is unpopular on account of the sickly appearance which it imparts to the meat, and blue glass has been used with some success. In

Holland the use of blue glass has, moreover, been extended to cow-houses with beneficial results. The glass, although of a distinctly different tint from Calorex, appears to share with the latter to some extent its power of absorbing the infra-red radiation of the sun, so that temperature effects may be partly responsible for the positive results obtained. The value of yellow glass cannot, however, be ascribed to such an effect. More information is obviously required on this most practical problem.

University and Educational Intelligence.

Birmingham.—The vacancy caused by the retirement of Prof. F. W. Burstall from the chair of mechanical engineering has been filled by the appointment of Mr. Samuel Lees. Mr. Lees studied at Manchester College of Technology and St. John's College, Cambridge. He took the Mathematical Tripos and afterwards did research under the late Prof. B. Hopkinson, being elected to a fellowship of St. John's College in 1912. He was Hopkinson lecturer in thermodynamics at Cambridge (1919–29) and director of engineering studies at St. John's College (1924–29). Since 1929 Mr. Lees has been consulting engineer to Messrs. Silica Gel, Ltd.

Leeds.—The University has instituted a diploma in public administration, the course of study for which will commence in October 1931. The course will extend over two winter sessions.

Sheffield.—The Council of the University has decided to appoint a professor of electrical engineering. It is hoped to make the appointment in time for him to take over his duties in the early part of 1932.

* * *

Mr. Sidney Weintroub, of St. John's College, Oxford, has been appointed an assistant lecturer in physics at University College, Southampton.

The Wilbur Wright memorial lecture of the Royal Aeronautical Society will be delivered on Wednesday, Sept. 16, at 9.15, in the Science Museum, South Kensington, by Mr. Glenn Martin, who will take as his subject "The Development of Aircraft Manufacturing".

The following scholarships for 1931 have been awarded by the Institution of Electrical Engineers: Duddell Scholarship (annual value £150; tenable for 3 years): C. H. W. Clark (Sevenoaks Grammar School); Silvanus Thompson Scholarship (annual value £100, plus tuition fees; tenable for two years): C. H. Lackey (Messrs. A. Reyrolle and Co., Ltd.); David Hughes Scholarship (value £100; tenable for 1 year): G. L. d'Ombrain (City and Guilds (Engineering) College); Salomons Scholarship (value £100; tenable for 1 year): S. H. Padel (Manchester College of Technology); War Thanksgiving Education and Research Fund (No. 1): grants of £50 each to F. J. Clark (East London College) and J. H. Wagstaff (University College, London); Thorrowgood Scholarship (annual value £25; tenable for 2 years): P. W. Ottley (Underground Electric Railway Company of London, Ltd.); Paul Scholarship (annual value £50; tenable for 2 years): W. T. Darwin (L.C.C. School of Engineering and Navigation).

Birthdays and Research Centres.

Aug. 16, 1863.—Prof. F. S. Kipping, F.R.S., professor of chemistry in University College, Nottingham.

Nearly thirty years ago the study of some organic derivatives of silicon was commenced, with the primary object of proving that compounds of the type $SiR_1R_2R_3R_4$ existed in enantiomorphously related, optically active forms. During the progress of this work, various interesting by-paths were encountered and, with the help of many students, some of these have been partly explored. The results have indicated that silicon analogues of many of the more important types of carbon compounds cannot be obtained, and that silicon is incapable of uniting with itself, with carbon, or with oxygen, by a 'double bond'. On the other hand, the formation of chains of silicon atoms, linked together directly or by an atom of oxygen, often takes place with unexpected facility, giving highly complex products, many of which cannot be isolated and identified.

Aug. 19, 1868.—Prof. W. Bulloch, F.R.S., Goldsmiths' professor of bacteriology in the University of London.

Ever since Lister (1869) introduced into surgery the principle of the antiseptic absorbable ligature in the form of catgut, this has always been a problem. Some years ago I was requested by the London Hospital authorities to investigate complaints regarding the sterility of samples of catgut sold in commerce. Much of the 'sterile' catgut was found not to be so, and the catgut sold by several manufacturers was found indeed to be uniformly (100 per cent) infected and presumably harmful. To remedy this so far as my own hospital was concerned, I carried out a systematic investigation of the methods of sterilising catgut, and this involved testing more than 30,000 ligatures. Two methods were found to be effective in producing sterile catgut. In conjunction with Messrs. Lampitt and Bushill, of the laboratories of J. Lyons and Co., a report was issued by the Medical Research Council, and the result was that surgical catgut was brought under the Therapeutic Substances Act, and the tests we had laid down were enforced. Two years' experience of the new conditions relative to the manufacture of surgical catgut in England and abroad has shown that at the present time the catgut is much better than was previously the case, and the risk of ligature infection in surgical operations has been greatly diminished.

In my leisure I devote my time to the study of the history of the sciences associated with medicine.

Aug. 19, 1874.—Prof. A. H. Reginald Buller, F.R.S., professor of botany in the University of Manitoba.

I am interested in the relations of fungi with various animals; and two species of Fungi Imperfecti, which attack and kill large numbers of larval nematode worms (*Strongylus* species, parasites of the horse) as these wriggle about in horse dung, are being investigated in my laboratory.

My chief occupation just now is the completion of the manuscript and the illustrations for another volume of my "Researches on Fungi". This volume, in part, will treat of *Pilobolus* and the ocellus function of its subsporangial swelling, *Sporobolomyces* regarded as a basidiomycetous yeast, *Tilletia tritici*, which causes the stinking smut disease of wheat, and *Sphærobolus stellatus*, a small gasteromycete allied to the puff-balls, which can shoot its ball of spores a horizontal distance of eighteen feet.

Aug. 19, 1885.—Prof. A. J. Clark, F.R.S., professor of materia medica in the University of Edinburgh.

We know something of the metabolism of the skeletal muscles, but practically nothing about the metabolism of cardiac and plain muscles. The latter group is, however, more important in certain respects than is the former.

The differences in function shown by the different types of muscles make it probable that their metabolic processes differ widely. Skeletal muscle is a very highly specialised tissue, whereas cardiac and plain muscles are somewhat less specialised. The metabolic processes of the latter group deserve, therefore, far more attention than they have hitherto received.

Scientific Aspects of the Unemploym Problem.

EVEN more perhaps than Dr. Miall's " H of Chemical Chemistry ", the progr of the recent jubilee meetings of the Socie Chemical Industry illustrates the remar extent to which, during the last fifty years science of chemistry has penetrated and transfo almost every section of industry, if not indeed public services. Examples are to be found i scientific papers presented at the meetings, w covered not only chemical industry generally such special sections of it as the dyestuff indu but also a discussion on fuel subjects which braced questions of fundamental importanc society in general as well to industry. Stri evidence of the widespread impact of science industry is to be found in the technical visits by members of the Society. These covered diverse industries as wallpaper manufacture, research laboratories of the General Electric Ltd.—which provide an outstanding example o industry created and continually expanded by application of scientific research—dry clean fine chemicals and drugs, gas, coke and tar, brew agriculture, foodstuffs, fuel research, the protec of metals against corrosion; while visits to National Physical Laboratory and the Chem Research Laboratory demonstrated the vital imp ance of scientific research in national life.

It is against such a background that the bearing of Sir Harry McGowan's president address to the Society of Chemical Industry, cussing the reaction of scientific and techni progress on the finance and economy of the mod State, is perceived. Scientific discoveries and th application in industry have dislocated the ma balance between industrial and agricultural p duction and have threatened the whole soc financial, and political structure of our civilisati Sir Harry McGowan uttered no idle warning wh he hinted at the possibility of our common civili tion perishing through our inability to control t forces which applied science primarily has create Under the influence of science, not only industry b also accepted views of trade and competition a changing their value, and policies such as free tra or protection acquire a new significance.

Sir Harry McGowan urged that the policy industrial co-operation which has developed notab in chemical industry under such forces should b extended into the more difficult field of internation co-operation—as indeed has already been done 'ew branches of industry, though with what s it is difficult as yet to say. As an aid to ontrol or development, Sir Harry McGowan ised a Minister of State devoted to the task omoting the co-ordinated reorganisation of industries, and beyond this an international cal council to provide chemical industry with ld-wide range. The effective rationalisation secured would stabilise development and co-ate or expedite research.

turn from the picture of industrial and inter-nal co-operation thus eloquently painted to fforts of Parliament during the past session pe with unemployment and the general in-al situation is to realise how far from com-urate with the rapidity of technological or tific advance in the last fifty years is the ence which representatives of science or of tific industry are able to exert on the direction ublic affairs. Examples of this have already the subject of comment in these columns. , the Royal Commission on Transport in its report made certain recommendations regard-oth road and rail transport which were intended sist the general economic development of the n. Neither in respect of the electrification burban services nor in the diversion of heavy ls traffic from road to rail have any adequate s been taken to give effect to the recommenda-s of the Commission, although both these re-mendations should encourage employment and recovery of the railways from their difficult ition. In the absence of a more scientific icy, it is still common for a heavy goods lorry do damage to a road in a few hours amounting several times the combined value of the lorry its load.

similar hiatus between knowledge and action sts in the fuel question. A really scientific sideration of the coal and fuel industries would viate considerably the difficulties in which the l industry finds itself. Lack of courage, how-r, remains the characteristic Government atti-de in 1931 as in 1926, and not even the grow- seriousness of atmospheric pollution or the ensity of the unemployment situation has driven rliament to examine the utilisation of our coal ources in the form of smokeless fuel or oil fuel a possible economic policy worthy of develop-nt. The fuel problem and the competition tween raw coal, gas, and electricity is still allowed develop along haphazard lines, without any tempt to plan and enact a scientific and economic tional policy. To this position no contrast could be more startling than the discussion on fuel subjects at the recent jubilee meetings of the Society of Chemical Industry, which was planned to elucidate definite answers to such questions as the probable effect upon the amount of coal raised, of the increasing use of oil, of the future development of the gas and electrical industries, of a large development of low temperature carbonisation, or of a general improvement of the standard of living. Only upon the considered answers to such questions can an adequate fuel policy be based, yet here again it is science and industry and not Parliament which is conducting the inquiry. The conference indeed took a sombre view of the prospects of any increased demand for coal, Dr. Lessing considering that a decrease in consumption is more probable, and even in the development of the hydrogenation process, prospects of an increased output of raw coal are not bright. Although international agreements might secure more lucrative prices, they are unlikely to affect the tonnage of coal raised. Lieut.-Commander Kenworthy's suggestion that scientific workers, economists, and business men should set up a representative body to examine the economic side of the coal problem was itself a confession that Parliament is not the instrument which will put coal mining on its feet. Essentially the plea was an admission that the fuel problem demands scientific treatment as an organic unit by the best brains of the country, unfettered by political ties.

When we pass to the direct contribution of the recent parliamentary session to the relief of unemployment, our present system of government shows to no greater advantage. For a sanctioned expenditure of up to £173,000,000 on emergency work for the relief of unemployment, work has been found for an additional 200,000 only, not allowing for any possible effects of discontinuing the safeguarding on gloves, lace, and cutlery. Such is the outcome not merely of this large expenditure of money but also of Parliament's endeavours to induce reorganisation of the coal, cotton, and iron and steel industries, Acts on housing, land drainage, and transport, and the expenditure of large sums on electrification, road improvement, and afforestation. There can indeed be no fairer comment on the situation than the recommendation of the Macmillan report that we should attack the task of capital development in England 'in a much more systematic and far-sighted manner than hitherto. An era of conscious and deliberate management must succeed the era of undirected natural evolution.

It is, of course, alleged by some that science itself causes unemployment, and that the increased production made possible by the mechanisation of industry under the influence of science is mainly responsible for our present difficulties. Superficial support may be found for such a view, but apart from the unescapable fact that industries such as the wireless industry—in which there is no unemployment—the electrical industry in all its branches, the automobile industry, the chemical industries, and aviation, which provide employment for millions of workers for whom otherwise there could be no industrial occupation, are the direct outcome of creative science and its application, the evidence of such industrial leaders as Mr. Henry Ford indicates that industrial leadership and continuous improvement in efficiency lead to industrial expansion and increased employment. The idea that there is only a limited amount of employment in the world has been revived in the present crisis, but remains a fallacy. The temporary unemployment due to displacement of workers during the genuine rationalisation of an industry, the permanent displacement of certain workers through the rise of a new industry such as the rayon industry, and the decline of the older textile industries, even though the final volume of employment is increased, tend to obscure the real issues, and the confusion is heightened by the failure of the industrialist either to foresee the problems and difficulties involved or to secure a minimum disturbance during the transition period.

The possibilities in the application of scientific method to the unemployment problem are indicated not only by the Macmillan report, which visualises a comprehensive re-building and re-planning policy for our larger towns and industrial centres, the re-planning and re-fitting of stable industries, and the electrification of railway systems, but also by the International Labour Office in its proposals for practical action on unemployment in Europe, which were recently submitted to the Commission of Inquiry for European Union. Without elaborating a definite scheme, the memorandum outlines such ideas as a definitely planned international road system to meet the probable requirements of rapidly increasing motor traffic and to provide connexions between the special roads for motor traffic which are at present being constructed everywhere independently in the most advanced countries of Europe; the co-ordination of regional systems of navigable waterways; the international distribution of electric power; and the concerted and uniform substitution on all European continental railways of a s
system of automatic coupling in place of the p
screw couplings, which are annually resp
for many fatal accidents. Schemes of thi
planned in advance as a definite programme

the worker can look for continued and adequ
employment.

'sychological Problem of Joan of Arc.

ial of Jeanne d'Arc. A complete translation ie Text of the Original Documents, with an oduction, by W. P. Barrett. (Broadway ieval Library.) Pp. viii + 352 + 12 plates. don: George Routledge and Sons, Ltd., .) 15*s.* net.

ERE can have been few historical events which have seemed more inexplicable than which made up the life of Joan of Arc. A it girl of eighteen profoundly affected the ies of nations. Such things seem impossible; hey occurred. The problem of Joan will ps never be completely solved. It may be possible to show that her history was y an unusual configuration of events, motives, personal characteristics which were each in selves neither unique nor startling. But Mr. ett's excellent translation of the documents ng to her trial enables even the layman to pt such an analysis.

ne of the leaders of the French, who followed may have been sceptical of her supernatural rs and have used her only on account of her nce with the people. Some of the ecclesiastics, burnt her, may have been genuinely concerned in upholding the authority of the Church and fending it against the dangerous and uncertain e of individual conscience. But rational ex- ations of Joan's effect upon her time in terms olitical motives and ecclesiastical theory can y solve half the problem. They leave the part ed by superstition and hysteria wholly un- ained.

oddesses or saints on one hand and demons itches on the other are both, anthropologically psychologically, aspects of the same idea. It ssible, as Miss Murray has argued, that Joan nated the goddess of a Dianic cult which had ved among the peasantry from neolithic s. But whether or not such a cult had actually ived, Joan was psychologically a demon to one ty and a goddess to the other. Now, modern chology has shown that these two ideas are jections of two aspects of the concept of the ther, one evil and terrifying, the other good and premely helpful, which survive in the unconscious om earliest infancy. From this fact these ideas rive their force.

To her enemies Joan was not only a political isance and a heretic; she was also a witch, nething infernally dangerous which must at all ts be destroyed. To her friends she was not only the creator of nationalism; she was a saint, perhaps even a goddess, who could not fail. There is a type of defensive nationalism, especially prevalent among the Latin races, which is clearly an expression of the Œdipus complex. To the unconscious, France became the persecuted mother, and the English and the Burgundians the violators from whom she was to be delivered. Joan, the Maid, gave this fantasy to the people As a saint or goddess she was also a symbol of the ideal mother, and therefore must have become identified with France. The fact that she was a virgin was important, as Voltaire observed, for, curiously enough, the unconscious generally likes to think of its mother as a virgin—one who has been threatened by the father but who has not yet yielded to him If she had been known to have given herself to any one man she would have lost her power over the rest. For the same reason the mother goddesses of antiquity were often unmarried—that is, they were either wholly chaste or universally promiscuous.

If Joan was the bad mother to the unconscious of her enemies and the good mother to the unconscious of her friends, to her own unconscious it seems probable that she was not a woman at all, but a rebellious son. The fantasy of nationalism is the fantasy of the son who, desirous of believing that his mother loves him only, imagines that she is the unwilling victim of his father from whom he will set her free. National leaders have been undoubtedly often inspired by such an unconscious fantasy; and when a woman displays the same symptom the suspicion at once arises that she may have unconsciously believed herself to be a man. Joan's transvestism was so persistent that it brought her to the stake. Therefore it can scarcely be rationalised as a protection against the soldiery among whom she lived. The loss of her male clothes or of her virginity might have destroyed the unconscious delusion of masculinity from which she probably derived much of her power.

Joan's voices appear to have been the projection of her own unconscious wishes. They told her to wear men's clothes and to deliver France. In them she implicitly believed, and so gained that confidence in her mission which inspired faith in her friends and fear in her enemies. Lastly, she had an intelligence of a high order, which must have helped to remove the doubts from those who might otherwise have thought her mad.

There have been many women with the Œdipus complexes of men which have been expressed in patriotic fantasies. There have been others who had voices which gave them an unnatural confidence, and yet others who have been intelligent. The combination of these three qualities in one person at a time when the political and mental life of the world enabled them to be effective were probably among the most important factors which went to make up the history of Joan of Arc.

Anthropology in Nigeria.

(1) *A Sudanese Kingdom: an Ethnographical Study of the Jukun-speaking Peoples of Nigeria.* By C. K. Meek. Pp. xxxiv + 548 + 64 plates. (London: Kegan Paul and Co., Ltd., 1931.) 25*s.* net.

(2) *Tribal Studies in Northern Nigeria.* By C. K. Meek. Vol. 1. Pp. x + 582 + 60 plates. (London: Kegan Paul and Co., Ltd., 1931.) 25*s.* net.

(1) THIS work on the Jukun of Northern Nigeria has been eagerly awaited by all those who were aware of Mr. Meek's study of this interesting people. Though these "studies were confined to a period of less than five months", no doubt he has been able to confirm and enlarge his knowledge from many sources in the last decade, during which he has had access to all the anthropological information collected throughout Nigeria. He has made excellent use of his opportunities, and the book may be regarded as authoritative and containing his considered opinion on the customs of the Jukun; in view of the haste with which the African, even in the Northern Provinces, is now shedding his old beliefs, it is unlikely that further researches will throw much additional light on them.

In an introduction of 21 pages, Mr. H. R. Palmer, formerly Lieutenant-Governor of the Northern Provinces of Nigeria and now Governor of the Gambia, discusses the affinities and history of the tribe. He would appear to place too much reliance on etymological similarities and on traditions and tales, some of which are probably of fairly recent Mohammedan provenance. Mr. Meek's treatment is more conservative, but, despite all, the origin of the Jukun is far from certain, though some facts give colour to their claim of a migration—at any rate, so far as the leading families are concerned—from Yemen, or Yeman, which to them includes all north-east Africa.

The Jukun kingdom was known as Kororofa, or Kwararafa, and was at the height of its power in the fifteenth to the seventeenth centuries, during which it is said to have captured Kano and Zaria, and to have penetrated into Bornu, Katsina, and even Gobir. Its capital, of the same name, was situated south of the Benue River, some three hundred miles south-south-east of Kano, and was abandoned a century ago, about the same time as the greater number of the towns were destroyed by the Fulani and Chamba. The tribe is now very small, numbering only some 25,000, living in scattered communities, mostly south of the Benue.

It is difficult to understand how this people, which to-day shows not the slightest warlike tendencies, could ever have formed a great confederacy, but no doubt their prestige was, to a large extent, due to moral and religious considerations, to the influence of their divine king. It is claimed that their power extended to the sea, but no evidence is given for this, and the far greater Aro theocracy, with its five million adherents, stood in their way.

Mr. Meek states that Calabar, the port to which the Aro exported most of their own—and probably the Jukun—slaves, "was known locally as Atakp or 'King of the Akpa' or Apa. For the Ekoi o these regions bore the same title as the Juk farther north". Akpa, however, is the na applied hereabouts to a large river, and it is un likely that it has any connexion with the Juku 'Apa', while the branch of the Ekoi settled here is called Kwa. Mr. Palmer (p. xix) and Mr. Meek (p. 16) are also incorrect in thinking that Dama "is a tribal name in the southern provinces"; according to the peoples of Ogoja province it was given to some of them by Hausa and others from the north.

The Jukun language is classified as belonging to the Sudanese group, which is enlarged to include semi-Bantu; out of 115 words, however, no less than 57 per cent are common to Bantu and Sudanese. Though little reliance can be placed on language to show the affinities of a people, this fact, together with their physical appearance as shown in the photographs, strengthens the belief that the mass of the people are of a Nigritic type; unfortunately the author took no somatic measurements.

The Jukun are still in the midst of changing from mother-right to father-right; there is no strict clan organisation and few traces of exogamy. The taboos as regards the use of personal names are stringently observed; even wives, who were wedded as virgins, may not thus address their husbands, though women who have previously been married can do so. The most interesting part of the book is that dealing with the divine king, who appears to be now regarded as an incarnation of the whole pantheon. His chief function is to secure plentiful harvests for his people, as he is the principal intermediary with the gods and ancestors on whom their growth depends; if he is out of favour with these, he is secretly killed. Apparently the normal reign of a Jukun king was about seven years, though a vigorous and popular man might live far longer.

Mr. Meek identifies both the Dindi (or soul) and the "spiritual guardian"—which seems to resemble what I have called the Over-Soul among the southern tribes—with the Egyptian *Ka*, but, even allowing for the considerable variation in the beliefs about this latter at different periods, there is a much larger content in the Nigerian idea, part of it unique. Heaven (*Kindo*) is regarded as "The House of Truth", and the earth-goddess Ama, who rules there, as a just and righteous deity.

The most interesting of the burial rites is the "releasing of the white grave cloth from the mouth", the purpose of which seems to be very similar to the Egyptian "opening of the mouth", [illegible] that the dead man may be able to speak in [illegible]ndo and inquire the cause of his death, which he will later declare to his living relatives at the ceremony of the Aku-Akwa, when the soul is formally requested to take up his abode in the bush and house shrines respectively.

According to the author, "A main cause for the firmness of the belief in the continuous existence of the dead is due to the conception of the necessity of the punishment of witches and sorcerers". The causality, however, is not apparent; the two beliefs, in survival and witchcraft, run in all probability side by side, as in most peoples, African and other.

A large—and, even in the reviewer's opinion, an excessive—portion of the book is taken up with comparisons of beliefs and practices in other countries, which will offend those scientists at home who consider that the field-worker should confine himself strictly to the people whom he is studying. Mr. Meek's assertions as to the close connexion of Jukun customs with those of ancient Egypt seem to be fully warranted. He is to be highly congratulated on the book, which is also well produced and illustrated, though some of the photographs might have been more appositely placed; few misprints have been noticed, but surely on p. 63 "the influence of the father's relatives is tending to decrease" should read "increase". The index is not so full as could be desired, which is the more regrettable, since the facts dealing with a single idea or custom are not always kept together.

(2) The second book under review, "Tribal Studies in Northern Nigeria", vol. 1, contains ethnographical notes on a large number of little-known peoples, dealing chiefly with their social organisation and languages. It is well for this information to be printed and made available for officials and scientists; fuller knowledge can be filled in as acquired. Perhaps the most interesting feature described is the sexual communism which is customary in some areas.

The Eket sacred lake, mentioned on p. 166, lies to the south-west, not to the north, of Calabar; this statement is referred to "The Golden Bough", where it is mentioned that the lake is near Eket in North Calabar. The illustrations are not so good as those in the Jukun book. An index will presumably be provided in the last volume.

P. AMAURY TALBOT.

Mathematics for Actuaries and Others.

(1) *An Elementary Treatise on Actuarial Mathematics.* By Harry Freeman. (Published for the Institute of Actuaries.) Pp. xiii + 399. (Cambridge: At the University Press, 1931.) 25*s*. net.

(2) *Some Recent Researches in the Theory of Statistics and Actuarial Science.* By Prof. J. F. Steffensen. (Published for the Institute of Actuaries.) Pp. vi + 52. (Cambridge: At the University Press, 1930.) 5*s*. net.

(3) *Probabilités et statistiques.* Par Dr. R. de Montessus de Ballore. (Leçons professées à l'Office National Météorologique de France.) Pp. ix + 211. (Paris: Hermann et Cie, 1931.) 60 francs.

(1) MATHEMATICS has been indebted to actuaries in the past for many valuable contributions in the fields of interpolation, finite differences, and statistical method. We have here an excellent treatise, by an actuary, on those branches of mathematics which are needed by the actuarial student. The author has held in mind the standard required to pass the examinations of the Institute of Actuaries, but has interpreted this standard in a broad way, with the result that we have chapters on elementary trigonometry, on functions and limits, and on differential and integral calculus, as well as those more especially required by the actuarial student, as are the chapters on differences, interpolation, approximate integration, and probability. The result is a model textbook. Proofs are clearly explained, and followed up by many illustrative examples, while the chapters end with a large number of well-chosen examples for solution by the student.

Apart from the needs of the student, we may anticipate that the research worker who has mainly relied in the past on Whittaker and Robinson's "Calculus of Observations" for the study of numerical mathematics will be able to supplement his reading with profit in the future from the text-book under review. The theory of statistics has not been dealt with, which seems a rather important omission, unless it is thought that this subject should preferably have a text-book to itself one of these days. It is not only on interpolation that many of our actuarial mathematicians have made important contributions to knowledge; papers frequently occur in the actuarial literature on points of statistical theory. The grounding that is furnished to the student on the subject of probability by the author, who is careful to avoid being dogmatic, should, however, be of great value to those who are going on to more advanced studies, as well as furnishing a ready tool for immediate use in life assurance calculations.

In the chapters on interpolation, importance is attached to the use of higher differences than the first, and to the study of the remainder term; and in this section reference is made to the fundamental work of Steffensen, made familiar to students in Great Britain through the English translation of his work on interpolation.

(2) Prof. Steffensen was invited in 1930 by the University of London to deliver a course of lectures, and he chose as his subject "Some Recent Researches in the Theory of Statistics and Actuarial Science". These lectures have now been published for the Institute of Actuaries by the Cambridge University Press. This is not a text-book in the accepted sense so much as a collection of notes, and it suffers a little from the heterogeneous character of the material with which the lecturer chose to deal. He has something to say on the place of mathematics in statistical and actuarial theory, and for the rest the book is a critical mathematical commentary on certain points of theory.

It is unusual to find an author setting out boldly to expose "errors due to neglect of the principle that theoretical assumptions should not contain contradictions". Interest in his section on "presumptive values of frequency constants" is shown by the way the matter was taken up and discussed by Dr. G. J. Lidstone in a recent issue of the *Journal of the Institute of Actuaries*. We feel that Prof. Steffensen has not been particularly illuminating in explaining the contradictions here, if indeed there are any. Other matters dealt with in the lectures are certain propositions in inequalities, and the theoretical foundations of various types of frequency functions.

(3) In "Probabilités et statistiques" we have a book of a different character. In his study of probability the author follows the traditional lines of Laplace, and his object is to reach the binomial distribution, of which he then gives the general theory. He applies this function to fit by means of moments a great variety of frequency distributions. The method has considerable success, but there are cases—as, for example, the distribution of barometric heights at Southampton—where the method proposed by the author is no more successful than were earlier efforts to fit Pearsonian curves. We wish that the author had used a sound test of goodness of fit in demonstrating the success (or non-success) of his formula; as it is, we are left in some doubt as to how his method compares with, for example, Pearson's Type I. distribution, to which there are strong resemblances. The work is largely the outcome of the author's own researches, and will be studied with profit by mathematical statisticians. JOHN WISHART.

Palæolithic Man in Egypt.

Prehistoric Survey of Egypt and Western Asia. Vol. 1: *Paleolithic Man and the Nile-Faiyum Divide; a Study of the Region during Pliocene and Pleistocene Times.* By K. S. Sandford and W. J. Arkell. (The University of Chicago Oriental Institute Publications, Vol. 10.) Pp. xv + 77 + 11 plates. (Chicago: University of Chicago Press; London: Cambridge University Press, 1930.) 22*s*. 6*d*. net.

THE Oriental Institute of the University of Chicago a few years ago began a prehistoric survey of Egypt and Western Asia under the direction of Dr. J. H. Breasted. It devoted attention first to the valley of the Nile and the Faiyum depression in the Egyptian desert, where the stone implements of prehistoric man have long been noticed lying on the surface. It assigned to two geologists, Dr. K. S. Sandford and Dr. W. J. Arkell, of Oxford, the task of discovering and mapping the deposits in which the various implements actually occurred. It has now published, as its first volume, a valuable, well-illustrated report on the results.

Drs. Sandford and Arkell are to be congratulated on having added a most important contribution to our knowledge of the history of the Nile valley in Lower Egypt during Pliocene and Pleistocene times, and so made it possible to understand the circumstances in which man first appeared in that region of Africa.

There are no traces of man in Lower Egypt during the Pliocene period, when the northern part of the Nile valley formed an arm of the sea and the Faiyum depression did not exist. The earliest stone implements are of the Chellean type and occur with characteristic Acheulean implements in an extensively preserved river-terrace in the Nile valley at from 70 ft. to 85 ft. above the present level of the river. The Chellean implements are more or less water-worn, while those of Acheulean type are as sharp-edged as if freshly made, so the former seem to have been derived from some still older deposit. Next, there are Mousterian implements of a rather late form found abundantly in a terrace about 25 feet above the existing Nile alluvium. The later terraces in the Nile valley, presumably containing the implements of Upper Palæolithic and Neolithic man, are actually buried by this alluvium and thus inaccessible to study.

Drs. Sandford and Arkell have fortunately overcome this difficulty by discovering that the terrace with Mousterian implements passes from the Nile valley through the Hawara channel into the Faiyum depression. It sinks a little towards the Faiyum, and seems to prove that in Mousterian times the depression was completely filled with a great lake which received water from the Nile. The whole country was then fertile and it was not until later Palæolithic times that desert conditions began, and they may not have reached their present state until the Neolithic period. In these later times the Faiyum lake began to shrink, leaving a succession of beaches as terraces marking the several shores as it gradually diminished to its present extent. The beaches, of course, away from the Hawara channel, are not obscured by later alluvial deposits, and so can be searched for any implements they may contain. A beach about 20 feet below the Mousterian level yields late Palæolithic stone implements of a peculiar local group which Vignard has named the Sebilian. Then follow beaches with Neolithic implements which have already been well studied and described by Miss G. Caton-Thompson and Miss E. W. Gardner.

The evidence on which the various conclusions are based is recorded in a series of remarkably concise chapters, which are illustrated by diagrammatic sections of the deposits and effective sketches of the different types of implements. Actual photographs of the country are also given in the plates. Dr. Breasted contributes a useful foreword, and the authors themselves add a summary which, with the aid of a coloured geological map, makes the whole work readily understood. A. S. W.

Short Reviews.

The Dynamic Universe. By James Mackaye. Pp. x + 308. (London: Charles Scribner's Sons, 1931.) 10*s.* 6*d.* net.

The complex structure of modern physics has caused many obscurities and inaccuracies to creep into the formulation of its epistemological presuppositions. Even the cosmological value of the principles and equations of relativity is difficult to extricate clearly from the mass of speculations, dimensional and non-dimensional, to which they have given rise. In undertaking a clarification of the confused conditions of theoretical physics, Prof. Mackaye has performed a very useful task; and this he does by providing critical answers to a number of pertinent questions such as the following: What is the cause of gravitation? Is matter a form of radiation? What is the cause of the Lorentz contraction? Why are not material bodies retarded in their motion through space? Has the theory of relativity superseded the law of causation? Is the acceleration of material bodies relative exclusively to other material bodies?

The variety of these questions shows the range and purpose of the author's inquiry. Yet, besides separating physics and metaphysics and explaining the one by the other, Prof. Mackaye has the ambition of presenting a cosmic theory dealing with the structure, and cause of change of motion, of material bodies. This attempt is based mainly on the radiation theory, which the author claims to fulfil the aspirations both of science and philosophy by reason of its unifying character. Although very suggestive, this portion of the book is less convincing, especially as the radiation theory in its present stage is a "rather blind groping for the truth". One might question also the author's final remark that "the explanation of nature's laws are physical, not metaphysical", in view of the fact that any explanation has to assume a number of constructive elements which are beyond the actual range of the particular theory seeking an explanation. The author, however, is himself fully aware of these difficulties, and the cautious presentation of his thesis should cause much useful thinking to philosophers and physicists alike.

T. Greenwood.

Rapid Methods for the Chemical Analysis of Special Steels, Steel-Making Alloys, their Ores, Graphites, and Bearing Metals. By Charles Morris Johnson. Fourth edition. Pp. xix + 729. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1930.) 37*s.* 6*d.* net.

In the fourth edition of this book, we are presented with detailed descriptions of the methods of analysis of steel, steel works materials, etc. Instead of re-setting the third edition, the author has incorporated new and improved methods in eighteen appendices occupying 176 pages rather more closely printed than the rest of the book. The only other material alteration made is in the chapter devoted to the determination of tungsten in low tungsten steel and the analysis of slags containing chromium, tungsten, and vanadium; this has been rewritten and re-set. Otherwise, the third edition is given unchanged.

The book is essentially a laboratory handbook; the methods are described in very great detail, necessitating, therefore, considerable repetition and reference to methods which are not given in full until later in the book, the pages for reference not always being given. Considerable space is occupied by descriptions of apparatus designed by the author, such as electric furnaces, rheostats, and carbon dioxide absorption 'bulbs', which can be made in the laboratory. The methods are described as rapid methods; but it is rather surprising to find that more use is not made of the electrolytic process for the determination of copper, as this method, although not 'rapid' in itself, can be carried out while the determination of the other constituents in, for example, a bearing metal is taking place.

The last three appendices are devoted to details in the preparation of steel for microscopical examination and the results to be observed in normal and abnormal specimens. In a work of this description, such details must be of necessity rather scanty, but, coupled with references to original papers, they serve as a useful introduction to the subject.

Articulated Locomotives. By Prof. Lionel Wiener. Pp. xv + 628. (London: Constable and Co., Ltd., 1930.) 42*s.* net.

An articulated locomotive is a locomotive in which one or more of the driven axles are able to take up positions where they do not remain parallel to the others and may take angular positions in curves. Such locomotives, once rarely seen, are now found on many railways. The causes for this are the need for more powerful locomotives, the need for using heavy locomotives on lines with permanent way of insufficient strength, and the demand for locomotives of sufficient flexibility to negotiate curves of small radius. Well-known forms of articulated locomotives include the Fairlie, the Mallet, and the Garratt.

One landmark in locomotive history was the Semmering Contest in 1857, for it was then that most systems of locomotive articulation first appeared. Since then makers in all countries have produced articulated locomotives, and of these a great deal of information is given in the book under notice. One of Prof. Wiener's objects was to establish a clear system of classification of types. In addition to the descriptions, sketches, and illustrations of the engines, the book contains alphabetical lists of locomotives, railways and builders, and a chronological sequence of inventions connected with articulated locomotives.

Mechanics of the Gyroscope. By Prof. Richard F. Deimel. (Engineering Science Series.) Pp. x + 192. (New York: The Macmillan Co., 1929.) 17*s.* net.

This book is intended primarily for engineering students, but will be found of use also by students of applied mathematics and physics who are interested in the practical applications of the gyroscope. As regards scope and standard it occupies a position between the exhaustive treatises of Gray and of Klein and Sommerfeld on one hand, and Crabtree's elementary book on "Spinning Tops and Gyroscopic Motion" on the other. About thirty pages of the book are devoted to a rapid survey of dynamical principles, though this would scarcely seem to be necessary in view of the existence of a sufficiency of good text-books on this part of the subject. Then follow chapters on rotation under no forces (the free gyro), and on the spinning top and its motion on a plane and under constraint.

The book concludes with a discussion of applications to various types of gyro-compass and stabilisers used in ships and mono-rail cars. This discussion occupies about a third of the available space, and deals very fully with such topics as the stability of the gyroscopic apparatus and the methods used for controlling its oscillations and diminishing the errors to which it is liable. The free use of illustrations and tables taken from actual practice has enabled the author to produce a most interesting and instructive introduction to the theory and practice of gyroscopic motion.

Positivismus und reale Aussenwelt: Vortrag, gehalten am 12. November 1930 im Harnack-Haus der Kaiser Wilhelm-Gesellschaft für Förderung der Wissenschaften. Von Max Planck. Pp. iii + 35. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1931.) 1·80 gold marks.

This is a striking addition to the much-discussed pronouncements of physicists on the philosophical bearings of their new theories. Prof. Planck reveals himself as an idealist, having many beliefs in common with Sir Arthur Eddington and Sir James Jeans. His exposition of scientific method, and his views on the principle of causality and on the problem of free-will are a penetrating analysis of certain fundamental questions which are still a puzzle to the philosopher. Though Prof. Planck's message is hopeful, it is doubtful whether it should be taken as the final explanation of modern physics. T. G.

The World Mapped: being a Short History of Attempts to Map the World from Antiquity to the Twentieth Century. By Dr. I. J. Curnow. Pp. vi + 104 + 10 plates. (London: Sifton Praed and Co., Ltd., 1930.) 5*s.*

This is little more than an essay on an important and vast subject, nor indeed does its author make any further claim. It succeeds, however, in giving an outline of the subject, in which the principal developments are traced and illustrated by reproductions of early maps. The map-makers of antiquity have most notice, and perhaps the monks of the Dark Ages, and their fantastic maps merit a little less attention than they receive in Miss Curnow's allotment of space. This restricts a little the treatment of more enlightened ages. As a whole, however, the work is useful and may be recommended. It contains a short bibliography.

Matter and Radiation.*

By Prof. F. G. Donnan, C.B.E., F.R.S.

THE title of this lecture might suggest a discussion of the greater part of physical and chemical science. It is proposed, however, to confine the following remarks to a consideration of certain views and theories concerning the reciprocal inter-conversion of matter and radiant energy.

Some twenty-five years ago Jeans proposed, as an explanation of the enormous energy radiated by the stars, the startling hypothesis that matter might, under certain conditions, suffer a process of 'annihilation', whereby a proton and an electron might coalesce, and, disappearing as matter in the ordinary sense of the word, be converted into energy of radiation. The basis of Jeans's hypothesis was given by the special relativity theory of Einstein, which showed that matter and energy can be mutually related. Thus the energy corresponding to a mass m grams of matter was found by Einstein to be equal to mc^2 ergs, where c is the velocity of light in centimetres per second. Similarly, if E be the energy in ergs of a given quantity of radiation, its mass in grams is given by the expression E/c^2. We may express Jeans's idea by means of the equation $P+E=$ Radiation, where $P=$ proton and $E=$ electron. Now the mass of $P+E$ is equal to the mass of a hydrogen atom, and this is equal to the reciprocal of the Avogadro number N, the value of which is known to be $6{\cdot}06 \times 10^{23}$. Hence it is possible to calculate the energy of the radiation produced in the above reaction.

The development by Einstein of Planck's quantum theory enabled Jeans to carry this calculation one step further. If we suppose that the coalescence of P and E produces one quantum of monochromatic radiation (one 'photon'), we know that the energy of this quantum is given by the expression $h\nu$ where h is Planck's constant of action and ν the frequency of the monochromatic radiation. We can now write Jeans's hypothesis in the form of an equation, namely, $mc^2=h\nu$, and this equation enables us to calculate the value of ν, since $m=\frac{1}{6{\cdot}06 \times 10^{23}}$, $c=3 \times 10^{10}$, and $h=6{\cdot}5 \times 10^{-27}$. This calculation gives as a result $\nu=2{\cdot}2 \times 10^{23}$, the corresponding wave-length being $\lambda=1{\cdot}3 \times 10^{-13}$ cm.

Twenty-five years ago no radiation of this high frequency was known to science. Recent investigations on the so-called cosmic rays, which reach us from all parts of the heavens, have shown, however, that this radiant energy of cosmic origin contains frequencies equal to and greater than the frequency calculated above. Such results indicate, therefore, that some such hypothesis as that of Jeans is very probable, and that in the depths of space phenomena are occurring which are capable of producing photons of extremely high frequencies.

In the subsequent development of his theory of stellar radiation, Jeans has propounded the interesting hypothesis that in the interior of stars and nebulæ there exist very large and complex atoms which are much more massive than any known to us in the earth. In these 'super-radioactive' atoms Jeans supposes that electrons circulating near the atomic nuclei occasionally fall into the nuclei and, combining with the protons, produce the energy of stellar radiation as a resultant of the 'annihilation' of matter, that is, of electrons and protons. These actions are regarded by Jeans as independent of temperature and characteristic of the complexity and instability of the massive atoms. I do not intend to follow here the later hypothesis of Jeans, and propose to deal with the reaction $P+E=$ Radiation as a *chemical* reaction occurring between *free* electrons and protons. This reaction, if it be possible, is certainly the simplest and most fundamental of all chemical reactions and therefore worthy of the closest study.

We may observe two things about such a reaction. It evidently does not occur under any except very unusual conditions, as otherwise the material universe could not endure for very long. We may suppose that some very intense source of 'activation' is necessary, such as an extremely high temperature or possibly very high velocities of collision due to extremely high electric fields. The reaction is a very strongly exothermic one, so that the reverse reaction would be likely to occur only at excessively high temperatures. Given a system consisting of free protons and electrons, a proton-electron 'gas', we may therefore imagine the reversible equilibrium

$$P+E \rightleftarrows \text{Radiation}$$

as occurring in a closed space at a given temperature, and endeavour to obtain some idea of the temperatures which would be necessary. Only photons of frequency equal to or greater than $2{\cdot}2 \times 10^{23}$ could transform into a proton-electron pair. If the temperature were such that the *hohlraum* radiation were rich in frequencies of this high order, we might expect the possibility of such an equilibrium, assuming that this temperature was high enough to 'activate' the forward reaction. Given such assumptions, there are two very simple ways of calculating a possible temperature. The well-known formula $\lambda_m T=0{\cdot}3$ gives the wavelength λ_m of the radiant energy of maximum density in a closed space at a temperature of T degrees on the Kelvin thermodynamic scale. The frequency ν corresponding to λ_m being given by the equation $c=\nu\lambda_m$, we obtain the result $T=\frac{0{\cdot}3\nu}{c}$. If we now identify ν with $2{\cdot}2 \times 10^{23}$, it follows that

$$T=\frac{0{\cdot}3 \times 2{\cdot}2 \times 10^{23}}{3 \times 10^{10}}=2{\cdot}2 \times 10^{12}\ {}^{\circ}\text{K}.$$

Thus in a closed space at a temperature of the order of 10^{12} K, that is, one billion degrees, it would be possible for the reversible equilibrium $P+E\rightleftarrows$ Radiation to exist. Under these conditions matter, in the form of protons and electrons, would be constantly dissolving into radiant energy, and simultaneously radiant energy would be constantly giving birth to protons and electrons.

---

* Digest of a lecture delivered to the Research Department of the Metropolitan Vickers Electrical Company on June 12.

Another approximate way of calculating the necessary high temperature is the following. We start with the well-known equation for the variation with the temperature of the equilibrium constant K of an ideal gas reaction, namely, $\frac{d\log K}{dT}=\frac{Q}{RT^2}$ where Q is the heat of the reaction. If Q does not vary with temperature, the integrated form of this equation is $\log K=\frac{-Q}{RT}+\text{constant}$, which we may write in the form $K=k_1e^{-Q/RT}$, where k_1 is another constant. In this form of the equation, Q and R refer to gram molecules. If we divide both these quantities by the Avogadro number N (that is, the number of molecules in a gram molecule) we can state the equation in a form referred to molecular magnitudes: $K=k_1e^{-q/kT}$, where $q=Q/N$ and $k=R/N$ (called the Boltzmann constant).

Now if q is an extremely large quantity, it is necessary that T should have a very great value if K is to possess an appreciable magnitude. We observe, for example, that $K=k_1/e$ if $q=kT$. Now although it is not possible in the present case to define the equilibrium constant K in the usual way, let us, nevertheless, apply the foregoing reasoning, and write therefore $q=mc^2=kT$, or $T=mc^2/k$. Since $m=1/N$ and $k=R/N$, this gives the result $T=c^2/R$. Recollecting that $c^2=9\times10^{20}$ and $R=8{\cdot}4\times10^8$ ergs, we get $T=10^{12}$ °K, which is approximately the same result as before.

We might have used the Planck radiation equation in these approximate calculations. We shall employ it now, however, for a somewhat different purpose. This equation gives the distribution of radiant energy E as a function of the wave-length, and we may write it for our present purpose in the form:

$$E_\nu=\text{const.}\frac{\nu^2}{e^{h\nu/kT}-1}.$$

In the present case

$$\frac{h\nu}{kT}=\frac{mc^2}{kT}=\frac{c^2}{RT}=\frac{10^{12}}{T},$$

so that we have

$$E_\nu=\frac{\nu^2}{e^{10^{12}/T}-1}.$$

For two different temperatures T_1 and T_2 and the same ν

$$\frac{(E_\nu)_{T_1}}{(E_\nu)_{T_2}}=\frac{e^{10^{12}/T_2}-1}{e^{10^{12}/T_1}-1}.$$

If we put $T_2=10^{12}$, $T_1=10^{10}$, we get

$$\frac{(E_\nu)_{T=10^{10}}}{(E_\nu)_{T=10^{12}}}=\frac{e-1}{e^{100}-1}=\frac{1{\cdot}7}{e^{100}}.$$

Hence, in comparison with the energy density of radiation of frequency $\nu=2{\cdot}2\times10^{23}$ at $T=10^{12}$, the energy density of this radiation at $T=10^{10}$ will be negligibly small. It follows, therefore, that the reverse reaction Radiation $\rightarrow P+E$ would be practically non-existent at $T=10^{10}$, though very marked at $T=10^{12}$. Thus if the temperature 10^{10} were high enough to activate strongly the forward reaction $P+E\rightarrow$ Radiation, matter (in the form of protons and electrons) would dissolve into radiation practically completely.

Quite recently, E. A. Milne has given an important theoretical treatment of the reversible thermodynamic equilibrium $P+E\rightleftarrows$ Radiation, employing for this purpose the quantum statistics of Fermi and Dirac. If n is the number of protons, or the equivalent number of electrons, present per cubic centimetre at statistical equilibrium, then Milne's result may be expressed in the form:

$$n=\frac{2^{\frac{1}{2}}}{h^3}[2\pi kT(m_e/m_p)^{\frac{1}{2}}]^{\frac{3}{2}}e^{-\frac{1}{2}\frac{mc^2}{kT}}$$

where h = Planck constant, k = Boltzmann constant, m_e = mass of one electron, m_p = mass of one proton, $m=m_e+m_p$. Employing the known values of the constants and changing to 10 as exponent base, Milne's equation reduces to:

$$n=0{\cdot}96\times10^{18}T^{\frac{3}{2}}\times10^{-\frac{2{\cdot}35\times10^{12}}{T}}.$$

The following short table gives a few of the results calculated by Milne by means of this equation.

T	n (No. of Protons per c.c.)	ρ_m (Grams per c.c.)	ρ_R (Grams per c.c.)
10^{10}	10^{-202}	$1{\cdot}65\times10^{-226}$	$0{\cdot}85\times10^{5}$
10^{11}	10^{11}	$1{\cdot}65\times10^{-13}$	$0{\cdot}85\times10^{9}$
10^{12}	10^{65}	$1{\cdot}34\times10^{10}$	$0{\cdot}85\times10^{13}$

In this table, ρ_m = density of matter and ρ_R = density of radiant energy. ρ_R is calculated from the equation $\rho_R=\frac{aT^4}{c^2}$, where a = Stefan's constant.

It will be seen that our former rough calculations are in qualitative agreement with Milne's results. Imagine hydrogen gas gradually heated up in an enclosed space. Then we have the following picture. As the temperature rises the molecules will be ionised and finally completely dissociated into atoms. With sufficient further rise of temperature the atoms will become ionised, and when this process is practically complete we shall have our proton-electron gas. We must now imagine that at some very high temperature the reaction $P+E\rightarrow$ Radiation sets in. Milne's results show that at $T=10^{10}$ this reaction will be practically complete. As the temperature rises still higher the reverse reaction, the 'birth' of matter from radiation, begins to be appreciable, and we see that at $T=10^{12}$ the equilibrium density of matter becomes equal to $1{\cdot}34\times10^{10}$ grams per c.c. The state of affairs at $T=10^{12}$ corresponds in fact to enormous densities for both matter and radiation.

We can never expect in our laboratories to attain to temperatures of this order of magnitude. Our only hope in this matter, as in so many other related problems of physico-chemical science, lies in the technical progress of electrical science. Only through the attainment and control of enormous voltages are we likely to obtain results equivalent to the very high temperatures discussed previously. Let us calculate, for example, the energy value of mc^2 in terms of electron-volts. We must write (where V = voltage and e = electron charge)

$$eV = mc^2 = \frac{c^2}{N} = \frac{9 \times 10^{20}}{6 \times 10^{23}} = 1 \cdot 5 \times 10^{-3}.$$

Now $e = 4 \cdot 8 \times 10^{-10}$ e.s.u. Hence $V = 0 \cdot 3 \times 10^7$ e.s.u. Since one electrostatic unit of voltage equals 300 volts, $V = 300 \times 0 \cdot 3 \times 10^7 = 9 \times 10^8$ or nine hundred million volts.

It does not follow, of course, that voltages of this enormous value would be necessary, since we only require electrical potential gradients sufficient to impart to protons and electrons the energies required for 'activation', that is, the energies required to overcome the repulsive forces which exist at very small distances. We might say, at a guess, that controllable voltages of the order of a hundred million volts would be likely to initiate an entirely new era in physico-chemical science. The future progress of this fundamental science lies, therefore, in the hands of the scientific electrical engineer. It is to be earnestly hoped that these advances will be made in England, the land where the electron and proton were discovered by Thomson and Rutherford, and the land where one hundred years ago Faraday discovered how to set electrons in ordered motion by moving magnetic fields.

If we turn back now to our enclosure in chemical and radiant equilibrium at a temperature of 10^{12} degrees, we know that there exists in such an enclosure a sufficient density of photons of frequencies equal to $2 \cdot 2 \times 10^{23}$ and upwards, that is, of photons which can transform into proton-electron pairs. Suppose that from such an enclosure there could escape a dense stream of radiant energy of frequencies lying between, say, $2 \cdot 2 \times 10^{23}$ and 10^{24}. Imagine a sufficiently dense stream of this type of radiation to escape into *cold* interstellar space, and perhaps there to encounter another similar stream. What might happen? Is it not extremely probable that matter would be generated? The reverse reaction radiant energy$\longrightarrow P + E$ does not *necessarily* demand a very high temperature. It would be enough if there existed a sufficient density of photons of frequency equal to or greater than $2 \cdot 2 \times 10^{23}$. Such a reaction would be, indeed, the most fundamental synthetic photochemical reaction. Now photons of such frequencies are known to be reaching our planet from all directions in space. It seems quite possible, therefore, that matter may be in process of generation in cold interstellar space, whereas temperatures such as 10^{12} could only be expected to occur in the hot cores of stars, as Milne has suggested.

Jeans and Eddington tend to emphasise the 'running-down' of the universe, the steady dissolution of matter into radiation. It seems likely, however, that, although the total effect may be such a running-down, there exist places in the universe where a 'running-up' may occur, even though this running-up be of a temporary nature. The universe is probably in a state of fluctuation. It is certainly large enough to permit very considerable local fluctuations, and such fluctuations are by no means incompatible with that general running-down process which the second law of thermodynamics seems to demand. It may be true that the universe, as a whole, is passing from a less probable to a more probable state, from a state of greater to a state of lesser organisation. This general drift, however, is quite compatible with intense local fluctuations in the opposite direction. The re-conversion of radiation into matter may be one of these.

Southern Whaling.*

IN "Southern Whaling" Sir Sidney Harmer reviews the present position of the whaling industry and summarises our knowledge, obtained largely as the result of commercial operations, of the biology of the great whales. The statistics, gathered with scrupulous care, show clearly the great concentration of modern commercial operations in the southern hemisphere, where on the average three-quarters of the annual world-catch of whales is obtained. Since hunting began in that region at the beginning of the present century, quite half of the world's catch has been made in the Antarctic, while African waters have contributed another quarter. Modern whaling operations, therefore, are conducted principally round the great ice barrier which surrounds the south pole.

Analysis of the species captured by the commercial vessels shows the great preponderance of finner whales in the catches, 90 per cent of which consists of the four species—Blue, Fin, Humpback, and Sei. Of these, the Blue and the Fin contribute on the average three-quarters of the total captures, so that the industry is largely dependent on the available stock of these two species. The annual world-catch of all species of whales has risen from 11,000 in 1919 to about 30,000 in 1929 and is still increasing, and the percentage of Antarctic Blue and Fin whales in the total world-catch has risen correspondingly from 63 to 85.

Recent researches into the life-histories of Blue and Fin whales have established that the period of gestation of these species is about a year, and that the young are born at the most every alternate year. Propagation, therefore, is slow. It has been noted that the percentage of sexually mature females in the catches is decreasing, while evidence has also been brought forward which points to a steady decline in the average length of whales captured in Antarctic waters in recent times. In connexion with the latter feature, it is to be remembered that, in whale hunting, the larger animals are deliberately selected. Now a decrease in the average length of a species inhabiting a self-contained area and subjected to intensive fishing operations is regarded as symptomatic of over-fishing, but in the case of Antarctic whales other factors—for example, seasonal movements, inter-area recruitment, and the possibility of variation in the routes of migration, about which little or nothing is known—have also to be considered, so that further research into these factors is necessary before it can be definitely stated that there is a serious decline in the stocks of whales over the whole Antarctic area. There appears to be justification, however, for the fear that the whale stock is being exploited detrimentally, and Sir Sidney Harmer expresses the opinion that the industry in Antarctic waters is rapidly approaching the peak, if indeed that point has not already been reached. New developments in pelagic whaling have vitiated methods of conservation of the whale stock hitherto adopted, so that conservation by international agreement or legislation would seem to be an urgent necessity both in the interests of the whales and of the industry.

---

* "Southern Whaling." By Sir Sidney Harmer. *Proceedings of the Linnean Society of London*, Session 142, 1929–30.

The great rise in the whaling industry within recent years began with this new phase of pelagic whaling, that is, whaling without licenses outwith territorial limits, with parent ships of large size fully equipped with the latest appliances for the production of oil and guano. Unlike the earlier floating factories, these ships are self-contained and the whole carcase of the whale is hauled on board over a slipway, now most efficiently fitted at the stern. The parent ships are attended by several 'catchers', and harbours are not absolutely essential, as re-fuelling and re-storing can be done at sea from the 'carriers', while unloading of oil and guano can also be effected. This has been made possible by the use of whale carcases as 'fenders', while wireless, wireless direction-finding, and wireless telephony enable 'carrier' and mother-ship to establish contact without difficulty. The cruising radius of these large ships, in contrast to shore stations, is enormous, and it is not surprising that hunting for whales has been effected right round the fringe of pack ice which streams off the great ice barrier surrounding the south polar regions.

Sir Sidney Harmer is of the opinion that there is some relation between the distribution of whales and seasonal temperatures, and lays particular stress on a correlation between the September mean air-temperatures (for example, at South Georgia) and the order in which the Blue and Fin whales reach their maxima during the immediately succeeding whaling season in the same locality. Mossman[1] also states, "It is certain that the varying temperature of the South Atlantic caused by the fluctuating quantity of polar ice induces changes in the volume, direction and temperature of the great ocean currents". Temperature in itself is not considered a limiting factor in migrations, but it is taken as giving some indication of the melting of the ice which, with the interaction of the ocean currents, results in the growth of the plankton on which whales feed. Researches into the food of whales have so far elucidated that both Blue and Fin whales are plankton feeders and subsist in the Antarctic almost entirely on Euphausians; but, as Sir Sidney Harmer remarks, "The prevalence of these Crustaceans at any time does not produce an identical behaviour in the several species of whales", but that, "each species has its own times and seasons".

The question of the migrations of whales is one of prime importance, but the problem still awaits solution. There are undoubtedly breeding and feeding migrations, and the supposition that in the southern hemisphere a southward migration is for feeding and a northward for breeding is probably correct. Nothing, however, seems to be known of the migration routes or of the extent of the northward retiral.

The monthly statistics of the whales captured in the dependencies of the Falklands show clearly that the Blue and Fin whales reach their maxima during the summer months in the Antarctic and during the southern winter off the African coast. The composition of the stock fluctuates considerably in any one season (say at South Georgia), so that it is obvious that there are several lines of convergence on this particular area. Normally, at all sub-antarctic and antarctic localities, large and fat individuals are caught at the beginning of the season. Later, thin whales predominate, while towards the end of the season fat individuals may be again in evidence. It is presumed, therefore, that the lean whales have come from poor feeding grounds, probably in the warmer sub-tropical waters, and that the fat whales have experienced good feeding grounds nearer the polar ice or within the ice zone. A certain percentage of whales remains in sub-antarctic areas during the southern winter, and those captured have been found to be sexually mature or almost mature, but, naturally, operations during this period cannot be carried out except on a very limited scale, so that the relative frequency of whales in sub-antarctic waters during this period cannot be estimated.

Sir Sidney Harmer has submitted the figures as gathered by him from various sources to statistical treatment and has given a few tentative interpretations. No complete explanation is possible from the available data as to seasonal movements, but the suggestion is put forward that the central point of the main concentration of the Fin whale is farther north than that of the Blue whale, which latter is assumed to be (and probably is) an ice-loving species. The statistics show clearly that there are definite years when the Blue whales are in excess in the captures and others when Fin whales are more abundant, and that these phases seem to be correlated with the fluctuating ice conditions. The adoption, therefore, of the September mean temperature as a means of establishing correlation has been actuated by these occurrences. Blue whale years seem to correspond with low temperatures and heavy ice conditions, and Fin whale years with the reverse. With regard to breeding seasons, all available knowledge, chiefly from a study of fœtuses, is again reviewed, and the interpretation, with which there is general agreement, is that pairing and parturition take place outside the usual hunting grounds and seasons.

Since the publication of Sir Sidney Harmer's paper on "Southern Whaling", there has appeared "International Whaling Statistics" for the ten-year period 1919–1929, which has been published at Oslo by the Norwegian Government on the recommendation of the International Council for the Exploration of the Sea. This contains the figures from the whaling industry throughout the world, and is the first of a series which will constitute a complete study of the whaling industry for the last twenty years. The figures employed in Sir Sidney Harmer's paper show sometimes considerable differences from those of the "International Statistics", though, taken as a whole, this does not affect the general trend of the argument. Attention may be directed, however, to one particular series of figures. In Table 6 of Sir Sidney Harmer's paper, the tabulated data represent the whales captured during the season 1928–29 by all countries, and not, as stated, by Norwegian companies only. An interesting feature in the presentation of the data in "International Statistics" is the average production of oil per whale. The oil production is here given in the form of Blue whale equivalents on the following basis: one Blue whale = 2 Fin whales = 2½ Humpbacks = 6 Sei whales. Previously a production of 75 to 80 barrels of oil per whale was considered a good average, but nowadays this has risen with the improved methods of extraction to more than a hundred. The more complete utilisation of the whale carcases by pelagic whalers is all to the good, but has added to the investigator's difficulties in that recent oil production figures are not comparable with those for earlier years, while the effect on oil production of any variations in condition or of decrease in the average size of the whales is also masked. The efficiency of modern 'plant' has also resulted in an improvement in the quality of the oil produced, and it is now possible to put the higher grades of oil direct on the market in a more or less colourless and odourless condition.

An interesting effect of the intensive whaling operations in the Antarctic is that exploration has incidentally received a new impetus, as it did in the early days of sealing, for example, of Weddell, Biscoe, and Enderby, and new discoveries of land are likely to be achieved. Scientifically, also, the exploration of new areas will extend our knowledge of the distribution and frequency of these finner whales.

---

Obituary.

PROF. ARCHIBALD BARR, F.R.S.

BY the death of emeritus Prof. Archibald Barr, on Aug. 5, in Glasgow, the engineering profession loses one of its ablest representatives in Great Britain.

Prof. Barr was born in Paisley in 1855. He was educated at Paisley Grammar School and the University of Glasgow, where he graduated in engineering science in 1876. Thereafter he spent eight years as assistant to Prof. James Thomson in the University of Glasgow, when he was called to the chair of mechanical engineering in the Yorkshire College (now the University of Leeds), where he spent five years and equipped and organised the engineering laboratory, making it one of the most up-to-date in the country at that time. In 1889 he was recalled to Glasgow as regius professor of civil engineering and mechanics in the University, in succession to the earlier holders of the chair—Lewis Gordon, Macquorn Rankine, and James Thomson.

Dr. Barr might then have settled down to the comparative ease of an academic life, but he found at Glasgow inadequate lecture rooms and a poorly equipped laboratory in the basement, and he had the vision to see that the science teaching of the future must develop along experimental lines; he therefore threw himself with characteristic energy and purpose into the work of arousing interest and collecting funds with which to build and equip an engineering college worthy of Glasgow as one of the most important centres of engineering activity in Great Britain. The result was the James Watt Engineering Laboratories, opened in 1900. Here he continued, until 1913, to lecture, to supervise laboratory instruction and research, and to inspire an ever-growing staff and body of students with the determination to understand the fundamental principles of engineering science and to apply these to the manifold problems that confront the engineer in the daily practice of his profession. In 1889, when he went to Glasgow, there were thirty-six engineering students at the University; when he resigned the chair in 1913, this number had increased to more than two hundred.

Dr. Barr did not confine his activities to the University, but undertook consulting work in the testing of engine and boiler plants, and contributed to the papers and discussions of the leading engineering and scientific societies in Glasgow and London. He served at different times as president of the Institution of Engineers and Shipbuilders in Scotland, the Royal Philosophical Society of Glasgow, and the Scottish Aeronautical Society; he supervised the first motor car reliability trials held in Scotland, in 1901; was convener of the engineering section of the Glasgow International Exhibition in 1901, and chairman of the committee which organised the first aviation meeting held in Scotland, at Lanark in 1910; while from 1921 until his death he was chairman of the governors of the Royal Scottish National Institution, at Larbert, for the care of mentally defectives.

The year after Prof. Barr's appointment to the chair of engineering at Yorkshire College, Dr. William Stroud went to the college as professor of physics. These two young men became close friends, and the partnership proved most fruitful of results. Prof. Barr brought to it his gifts of mechanical invention and organising ability; Prof. Stroud, his flashlight penetration to the scientific core of a problem. In 1888 they decided to carry out a research on the mechanical equivalent of heat, but immediately thereafter they chanced upon an advertisement by the British War Office calling for a range-finder to measure ranges for gunfire, and in three weeks' time the essential features of the modern instrument had taken experimental form. For some years they worked at the development of the instrument, Prof. Barr making many of the parts with his own hands, and himself adjusting them from a platform on the roof of his house in Glasgow. In 1892 the first naval range-finder was built and tried on board H.M.S. *Arethusa*, and at once demonstrated its value to the Service; from that time the demand for such instruments steadily increased. In 1895 a small workshop was opened in an old stable, and later, another old building was occupied in the same neighbourhood. In 1904 the first part of the present factory building of Barr and Stroud, Ltd., was opened at Anniesland, on the western outskirts of Glasgow, with about a hundred workmen. It grew by 1914 to a factory with 900 men, supplying naval and military instruments to the British Government and nearly every foreign Power; while during the War, the main building was extended and two new buildings added to provide room for more than 2000 workers.

Prof. Barr took the keenest interest in all the problems of manufacture and factory development, visiting the United States in 1896 to learn something of their machine methods, and installing the first American milling machine to come to Scotland, two years later. He initiated the scheme of welfare work in the factory, sick benefit, recreation clubs, dining hall, and the use of the premium system in encouraging output.

The extended use of the range-finder on board ship made it imperative to control the fire of the guns; in 1905, Prof. Barr invented a step-by-step motor for signalling electrically from range-finder to gun, and from that date onwards many instruments were designed and patented which have gradually developed into the intricate fire-control system of the modern warship. An electrically operated torsion-meter for measuring the power developed by large prime movers was developed in 1912.

The War inevitably involved the firm of Barr and Stroud in greatly increased production of its usual work, and in this activity Prof. Barr took his share, but he also developed a number of instruments for military and naval use—the torpedo depth recorder, the rangetaker-tester, a bomb-dropping sight for aircraft, the submarine periscope—and took a keen interest in the manufacture of optical glass by improved methods. After the War, the attention of his firm was necessarily turned towards civilian work, and he perfected Dr. E. E. Fournier d'Albe's optophone for enabling the blind to read ordinary type, and a series of instruments for producing contour maps from photographs taken from an aeroplane, by which means survey work in new and unexplored countries has been very greatly simplified.

Prof. Barr was elected a fellow of the Royal Society in 1923, was a member of the Institutions of Civil and of Mechanical Engineers and the Institute of Metals, and was made doctor of laws of the University of Glasgow in 1914.

Prof. Barr will be remembered by his many students for his clear, direct, convincing explanations of the fundamental principles underlying any problem. He was not content to teach engineering as a mere branch of applied science, but aimed to develop in his students the power of thinking out for themselves the laws of science on which the particular work of the moment was based. He was a ready and lucid speaker, and drew upon a fund of humour and wide human sympathies which enabled him to command the interest and constant attention of his classes and to get into close touch with his students individually outside the lecture room. From boyhood he showed inventive talent, and all his life his mind was occupied with the solution of a long series of mechanical problems; while to the development of his patents on a manufacturing scale he applied an integrity which would not brook the least lapse from workmanship of the highest class. He brought to the management of his business a well-balanced judgment, a rapidity of thought that enabled him to come to a sound conclusion quickly, a clearness of mind by which he distinguished the commercial and financial aspects of a problem from the practical and scientific, and a sympathy with his fellow-workers and employees which has found expression in a workshop and organisation where every facility for the well-being of those engaged in the work is provided. His death will be deeply felt by the members of his family, his daughter and two sons (his wife died three years ago, and his second son was killed in France in 1915), by his business associates, and by a wide circle of friends and past students.

WE regret to record the death of Mrs. Howes, widow of the late Prof. G. B. Howes, who succeeded Huxley at the Royal College of Science. Mrs Howes died in Kenya Colony, at the home of her daughter, Mrs. Rae, on July 4, aged seventy-nine years. Forty years ago she made the home of her husband a resort for the younger school of biologists, and did much to forward the cause of modern biology.

WE regret to announce the following deaths:

Prof. W. E. Dixon, F.R.S., University lecturer in pharmacology at Cambridge and formerly professor of pharmacology in King's College, London, on Aug. 16.

Prof. J. W. Hinchley, professor of chemical engineering in the Imperial College of Science and Technology and secretary of the Institution of Chemical Engineers, on Aug. 13, aged sixty years.

News and Views.

THE results of the explosions made by the German Greenland Expedition to determine the thickness of the Greenland ice-cap have been awaited with much interest, owing to their widespread geographical and geological bearing. Two theories have been advanced as to the structure of Greenland. According to one theory, it is a high plateau capped with ice, and the rapid flow of the Greenland glaciers is due to their steep gradient. According to the rival view, Greenland, like Ireland, is a saucer-shaped land, consisting of a rim of mountains with the central hollow filled by ice, which flows outward over the surrounding highlands. Carvill Lewis adduced Greenland in support of the assumed covering of the Irish Sea by a dome of ice which then flowed over the Welsh mountains to the height of 1300 ft. Croll claimed that the Greenland ice was as thick as its height above sea-level, in support of his view that the ice at the south pole is 24 miles thick. Croll's estimates of the thickness of the Greenland ice-cap were declared impossible, in accordance with Lord Kelvin's calculations as to the maximum possible thickness of ice.

THE German Greenland Expedition under the late Prof. Wegener has now tested the thickness of the ice by artificial earthquakes, and the results have been announced by a telegram published in the *Times* on Aug. 13. The largest single charge fired was 74 kgm. of dynamite: 25 explosions were made, and the resulting waves observed. The control station was on lat. 72° N., midway between the eastern and western coasts, and therefore at the geographical centre of Greenland. The height there is 9800 ft. above sea-level. From the time taken for the return of the explosion-wave reflected from the base of the ice-sheet, it is calculated that the ice is 8800 ft. thick. The rock floor, according to this result, is only 1000 ft. above sea-level. The ice 38 miles inland, at the height of 6000 ft. above sea-level, is from 2300 ft. to 3000 ft. thick, so that the rock floor is there about 2000 ft. higher than in the interior. These experiments tend to support Croll's view that Greenland is saucer-shaped, and that the internal ice-cap is much thicker than has been claimed as physically possible. To what degree the explosion-wave results are trustworthy will be considered when the details of the experiments and calculations are available; but the ice is obviously much thicker than was expected on the conception that Greenland, like Labrador, is a high plateau with a marginal mountain range.

THE subjects to be dealt with by Section G (Engineering) of the British Association during the London meeting have been broadly chosen from three separate points of view. That the meeting marks the centenary of the Association is shown by the presidential address by Sir J. Alfred Ewing, which is, at the same time, the Bramwell Trust Lecture. In this Sir Alfred will deal with the position of prime movers in 1931. Prof. Elihu Thomson will speak on "Pioneering in Electrical Engineering Fifty Years Ago", and Sir Robert Hadfield will describe "Faraday's Work in Ferrous Metallurgy". To reflect the activities of the Association in all parts of the British Commonwealth, papers are to be given by: General C. H. Mitchell (Canada), "Engineers' Contributions to Canada's Development"; Mr. A. L. Egan (South Africa), "Methods of Improving the Kata Conditions of Atmospheric Air in Deep-level Mines". Lastly, since the Association is meeting for the first time in London, the special engineering interests of that city are to receive attention. London is, practically speaking, the centre of many activities in the sphere of aeronautics. The research work in this sphere at the National Physical Laboratory and at the Royal Aircraft Establishment, South Farnborough, will be touched upon by Mr. E. F. Relf and Mr. R. McKinnon Wood, who will respectively describe the new wind tunnels at these two establishments. Col. the Master of Sempill will give a paper on "Motorless Flight". These three papers are correlated with demonstrations: the wind tunnels by the visit to the National Physical Laboratory, and "Motorless Flight" by the gliding demonstrations to be given at Feltham Air Park on Sunday, Sept. 27.

FURTHER subjects to be discussed in Section G of the British Association which are connected more or less closely with London are: "Acoustical Problems of Broadcasting Studios", by Mr. Noel Ashbridge, of the British Broadcasting Corporation, and "London Tunnelling Problems", by Mr. H. H. Dalrymple-Hay. These papers, too, are combined with appropriate visits and demonstrations. Apart from these three special aspects, other important subjects of a general nature are included in the programme. Dr. W. Rosenhain will speak on "Metals and Alloys in relation to Engineering Progress", and Prof. F. C. Lea will present a paper on "The Effect of Temperature on some of the Physical Properties of Metals", these dealing with the metallurgical side. Sir David Milne-Watson, on "The New Gas Industry", will refer to some aspects of the important national question of fuel utilisation. Mechanical and manufacturing engineering are represented by Prof. E. G. Coker's paper on "Force Fits and Shrinkage Fits"; civil engineering by Prof. C. F. Jenkin, who will describe his "Earth Pressure Investigations"; while Prof. Julius Hartmann (Copenhagen) with his paper on "Jet Rectifiers" will deal with an important aspect of modern electrical engineering.

A CORRESPONDENT, writing from Loughborough on Aug. 6, mentions having seen a fully-grown cuckoo about his house for several days; on the above date it was perched on some railings along with about twenty sparrows, and being fed by a wagtail. Such an appearance of the yearling cuckoo is quite to be looked for at this time of year, but the fact that it has been deemed worthy of notice is worth recording, as it shows that the great difference in habits between the young cuckoo and the adult is not generally known. The old bird is notoriously secretive in its ways—so much so that it is literally only 'a wandering voice' to 99 per cent of those who know of its existence. But the yearling exposes itself quite freely, is easily approached, and may be seen almost anywhere; in two summers a specimen was seen perched on the top of the Small Waders' aviary which used to be behind the Lion House in the Zoological Gardens. As the build of the cuckoo—long-winged and short-legged—is that generally characteristic of birds which hunt in the open, the behaviour of the yearling is more in accordance with what one would expect from its structure than is that of the adult. Evidently, however, during the bird's progress towards maturity and its travels to and sojourn in the south, it finds it expedient to conceal itself, and retains the habit; possibly the chief elimination the species suffers is by the persecution of birds of prey, which compels individuals to this change of customs, as the cuckoo appears not to suffer from starvation in spring or to be compelled to board ships when on passage—common misfortunes with others of our migrants. The wagtail above alluded to had, no doubt, reared the cuckoo, and the sparrows would have been attracted by their curiosity at a strange bird, often popularly mistaken for animosity, which they rarely display.

A REPORT by Miss D. A. E. Garrod on work on the British School of Archæology in Palestine during the past season appears in *Man* for August. Miss Garrod herself has been engaged in excavating the Mugharet-el-Wad, the largest of the Wady-el-Mughara group of caves, close to the rock basins which were uncovered in the previous season. A series of mesolithic burials has been found with circlets of beads of bone and shell still in place on the skeletons. The better preserved one, which has been removed in one piece, will go to the Palestine museum as an exhibit. On the skull are the remains of a cap strung with dentalia shells, while the lower jaw is full of bone pendant beads. The skeleton lay in a contracted position with one arm across the body. Of the other excavations, Mugharet-el-School is being carried out by Mr. Ted McCown. He has found an interesting Mousterian industry, and at the end of last May brought to light the skull and lower jaw of a young child, three to four years old (see NATURE, June 6, p. 865). The end of a child's humerus was revealed in the hard block of Mousterian breccia. This has now been sent whole to Sir Arthur Keith, in the hope that it may be found to contain the whole skeleton. At Mugharet-el-Tabou is a purely Mousterian deposit of great depth. Its great interest at the moment consists in the fact that it contains well-preserved fauna associated with the Mousterian—at present little known for this region. At Mugharet-el-Kabara, Mr. Turville Petre is excavating Zichron Jakob, a cave ten miles from Wady-el-Mughara. A mesolithic horizon has produced bone sickle handles with carved animal heads at the top, many bone harpoons, and various pieces of carved bone and stone, some of which, it is hoped, may be on exhibition later in London.

THE farming industry in Germany is far from flourishing at the present time. Instead of this preventing the development of new industrial material, it seems, judging from the large number of new agricultural devices shown at the recent show in Hanover, to be acting as a spur to further improvements. In the *Electrician* for July 31, R. Borlase Matthews describes some of the novel machines shown at this agricultural exhibition. Manufacturers are providing machines likely to reduce the costs of production, and the farmer is doing everything to increase the cultivated area and farm the land more intensively, so as to lower the total cost per unit produced. The number of new implements shown was nearly two hundred, and there were 5300 machinery exhibits, numbers which far surpass anything seen at shows in Great Britain. Electrically operated apparatus was very much in evidence, large scale demonstrations being given of equipment suitable for dairying, poultry-keeping, etc. An ingenious device known as the 'rain-cannon' is used for watering fields. It consists of a jet mounted on a cylindrical pressure tank. The upper portion of the tank is filled with air, which is compressed by the water until there is equilibrium. When this is attained, a valve situated in the nozzle opens an orifice. Owing to the sudden release, the air pressure ejects the water in a powerful jet to a considerable distance and at the same time moves it round slightly. This method is a great improvement on the old sprinkler and pipe-line methods. A small rain-cannon requiring only a pressure of two or three atmospheres to work it was a very popular exhibit. Pneumatic transport methods for transporting hay from the barns are coming into use owing to their convenience. A device was shown which supplied concentrated feed to the horses in stables twice a day. It was entirely automatic, requiring charging only once a week.

IN the *University of Colorado Studies* for April 1931 there is an interesting paper by Prof. Kenneth Field on the effects produced by interconnexion of electric light and power supply companies. The tendency in America is for the small companies to unite and form large companies. For example, twenty large companies control more than fifty per cent of the total supply. Just as with the 'grid' in Great Britain, the economies arise from the decrease in the consumption of fuel per unit power generated, the more economical maintenance that can be attained, and what may be described as the substitution of capital for labour. In large steam stations, evaporators for distilling water can be used to prevent scale-forming materials from entering the boilers, and this reduces the maintenance costs. Mechanical stokers, coal and ash handling machinery, coal bunkers, etc., considerably reduce the manual labour required. When water is available for condensing purposes, steam generating stations are located at the coal pits, and thus the cost of transport is lowered. Savings in reserve capacity are facilitated by making temporary service from distant plants possible. During a recent drought in North Carolina, industries in that State which were dependent upon electric light and power were kept in operation by energy received through interconnexion with the Southern Company, operating in South Carolina. This company had no surplus power, but obtained from the Georgia Company the equivalent of the power which it passed on for use in North Carolina. In turn the Georgia Company received from the Alabama Company the equivalent of the energy it gave to the Southern Company. In effect, therefore, the North Carolina industries were kept going by electricity generated in the State of Alabama. The power was not actually transmitted, but the effect produced was the same as if it were.

A NEW scientific journal which marks an important stage in the geological survey of China has appeared under the name of the *Soil Bulletin*, published for the University of Nanking and the China Council of the Institute of Pacific Relations by the Geological Survey of China. Two numbers have appeared to date, the first in December 1930 and the second in March 1931; and both make contributions of interest to a subject which has received little scientific attention. Soils have distinctive morphological characters, and their classification on the basis of their own features, rather than from the point of view of their origin, is more likely to be of value to the agriculturist. A preliminary reconnaissance of a portion of the soils of China was carried out by Prof. C. F. Shaw in 1930, and this revealed the presence of nine soil regions. Of these, three are large areas of primary soils and six are composed exclusively of secondary soils. It was found that the geological origin of the soil material was subordinate to climate in determining the broad general soil regions, but within the regions it was of much importance. Mode of formation has had a dominant rôle in determining the characteristics of those regions which are composed mostly of alluvial sediments, though both climate and geological origin have naturally also had much influence.

AT the Congrès International du Bois et de la Sylviculture, which was held in Paris on July 1–5, an International Association of Wood Anatomists was formally constituted. This was the outcome of an informal meeting of wood anatomists which was held at Cambridge on the occasion of the fifth International Botanical Congress, in August 1930. At that time it was not found possible to do more than appoint a committee to consider the question of organisation and to report to the next conference, which was provisionally fixed for July 1931, in Paris. The Committee's report included a draft constitution, which was finally adopted at an open meeting held on July 4 last. The Committee was then empowered to enrol members and to carry on the affairs of the Association until such time as the statutory Council shall have been appointed. The secretary to the Committee is Prof. S. J. Record, Yale University School of Forestry, New Haven, Connecticut, United States, and the British representatives on the Committee are Mr. E. H. B. Boulton, Department of Forestry, University of Cambridge; Dr. L. Chalk, Imperial Forestry Institute, Oxford; Mr. B. J. Rendle, Forest Products Research Laboratory, Princes Risborough, and Mr. M. B. Welch, Technological Museum, Sydney, Australia.

IN 1911 an International Hygiene Exhibition was held at Dresden, and in 1930 a second International Exhibition was the appropriate occasion for the opening of a permanent museum of hygiene in that town. Since the first exhibition, almost revolutionary changes have taken place throughout the whole field, so that the 1930 exhibition presented quite a different picture from its predecessor. Its sections included the hospital, physical culture, occupational hygiene, psychic life and hygiene, woman and child, care of health, nourishment, clothing-hygiene, and sanitary and dwelling conditions. The aim of the Museum, organised as a registered association, is to convert the greatest possible number of people to a systematic and continuous care of their health, not merely by imparting instruction, but also by influencing them to think hygienically for themselves. Various sections are devoted to press and publication propaganda, teaching apparatus, lantern-slides, travelling exhibitions, health service, and so on. An illustrated article in the *Museums Journal* for July gives in some detail an account of this important institution.

AN explanatory circular (1208) has been issued by the Ministry of Health respecting the *Memorandum* (153/M.C.W.) on birth control issued in March. It is emphasised that local authorities have no general power to establish birth control clinics as such. Under the Maternity and Child Welfare Act, 1918, facilities for birth control advice at a centre are limited to married women already in attendance as expectant or nursing mothers in whom further pregnancy would be detrimental to health. Under the Public Health Acts, gynæcological clinics may be established and contraceptive advice may there be given to married women in attendance for a similar reason. It is considered undesirable that a gynæcological clinic should be established at a maternity and child welfare centre; such a clinic should be provided in separate premises or at a hospital. Contraceptive advice should not be regarded as falling within the scope of the normal duties of the medical officers of a local authority, who should be free to undertake or to decline it.

THE further issue in the Ministry of Agriculture's new series of bulletins includes one (No. 13) on "Home-grown Feeding Stuffs" by Dr. H. E. Woodman, the object of which is to indicate how the farmer's own produce may best be used in the rearing of stock. From a comparison of the relative cost of some home-grown and purchased feeding stuffs, it is evident that it may pay the farmer better to retain his own potatoes and corn for home consumption rather than to sell them and have to purchase maize meal. A general description follows of the composition, feeding value, and uses of a large variety of common home-grown foods, such as cereals, hays, forage crops, silage, potatoes, and sugar beet by-products, and rations suitable for different types of stock are supplied. In conclusion, a comparative table is drawn up showing the composition and feeding values of various winter forage crops and pasture grass, from which it is evident that kales in particular should prove satisfactory substitutes for pasturage. Copies of the bulletin may be purchased direct from the Ministry of Agriculture, 10 Whitehall Place, S.W.1, price 8*d.* post free.

The Indian Journal of Veterinary Science and Animal Husbandry is the title of a new quarterly journal the first part of which has recently been published for the Imperial Council of Agricultural Research, New Delhi, India. The annual subscription, including Indian postage, is Rs. 5, or 8*s.* 3*d.*, which should be sent to the secretary of the Imperial Council. The aim of the journal is to encourage practical investigations of economic value, and actual notes of practical experiences and clinical observations, rather than abstruse articles on research, are what are required, though reviews and abstracts of current work will be included. This first part contains an article by H. Cooper on anti-rinderpest inoculations, and other papers and abstracts on diseases and infections of cattle and other animals.

It is announced that Lord Ilchester and Prof. J. Stanley Gardiner have been elected trustees of the British Museum in succession to Lord Ullswater and Lord Chalmers, who have retired.

After consultation with the Lord President of the Council and the president of the Royal Society, the recently formed Agricultural Research Council has appointed Sir William Dampier to be secretary of the Council. Mr. E. H. E. Havelock, of the Development Commission, has been appointed assistant secretary.

The nineteenth annual meeting of the Indian Science Congress will be held in Bangalore on Jan. 2–8, 1932, under the presidency of Rai Bahadur Lala Shiv Ram Kashyap. The following have been elected sectional presidents; agriculture, Mr. G. N. Rangaswamy Ayyangar; mathematics and physics, Prof. Ganesh Prasad; chemistry, Prof. P. R. Ray; zoology, Prof. D. R. Bhattacharyya; botany, Dr. Haraprasad Chaudhuri; geology, Mr. Percy Evans; medical and veterinary research, Lt.-Col. A. D. Stewart; anthropology, Mr. J. P. Mills; psychology, Prof. N. S. N. Sastry. Further information can be obtained from the General Secretary, 35 Ballygunge Circular Road, Calcutta.

The Association of Special Libraries and Information Bureaux will hold its annual conference at Lady Margaret Hall, Oxford, on Sept. 18-21, under the presidency of Mr. H. T. Tizard. Some problems of professionalism will form the subject of a lecture by Prof. A. M. Carr Saunders, and Mr. B. M. Headicar will discuss practical methods of arrangement, indexing, and routine in the business library and information bureau. Other subjects included in the programme are "International Abstracting and Indexing" by Sir Frederick Nathan, "Films as a Medium of Information in Education" by Mr. F. A. Hoare, and "Agricultural Economic Information" by Mr. J. P. Maxton. On Sept. 20, Sir Francis Goodenough will give a short address on the Report of the Board of Education Committee on education for salesmanship.

A great earthquake was recorded in the observatories of Great Britain on the evening of Aug. 10. At Kew, the first impulses occurred at 9 h. 28 m. 21 s. p.m., G.M.T. The records indicate that the origin was about 4000 miles north-east by east of Kew, or near the Altai Mountains in Mongolia, and this position is confirmed by reports that it was about 2100 miles from Bombay. An earthquake on Aug. 16 which shook the city of El Paso and was widely felt in Texas and New Mexico was recorded as a small disturbance at Kew Observatory. The first impulses at Kew occurred at 11 h. 52 m. 4 s. G.M.T., and the records indicated that the epicentre was about 5300 miles away. Among other recent earthquakes, one of the most interesting occurred on July 18, in the Mississippi valley (*Daily Science News Bulletin*, Science Service, Washington, D.C., July 20). Its centre was close to New Madrid, the scene of the great earthquakes of Dec. 16, 1811, and Jan. 23 and Feb. 7, 1812.

Applications are invited for the following appointments, on or before the dates mentioned:—An assistant lecturer in mechanical engineering at the Technical College, Bradford—The Principal, Technical College, Bradford (Aug. 25). A principal of the Neath Mining and Technical Institute, and an assistant at the Caerphilly Mining and Technical Institute and Junior Technical Day School, with good honours degree in science—The Director of Education, County Hall, Cardiff (Aug. 25). A laboratory steward at the Technical College, Coatbridge—The Director of Education, Lanarkshire House, 191 Ingram Street, Glasgow (Aug. 26). A county librarian under the Durham County Education Authority—The Director of Education, Shire Hall, Durham (Aug. 27). Chemical laboratory assistants at the Royal Arsenal—The War Department Chemist, B.47, Royal Arsenal, Woolwich, S.E.18 (Aug. 29). An assistant librarian in the University of Birmingham—The Secretary, University, Birmingham (Sept. 5). A demonstrator of biology at St. Bartholomew's Hospital Medical College—The Dean of the Medical College, St. Bartholomew's Hospital, E.C.1 (Sept. 10). An assistant at the College of Estate Management for lecturing on town planning and road-making—The Secretary, College of Estate Management, 35 Lincoln's Inn Fields, W.C.2 (Sept. 14). A Milroy lecturer at the Royal College of Physicians for 1933—The Registrar, Royal College of Physicians, Pall Mall East, S.W.1 (Sept. 21). A handicraft instructor under the Lincolnshire (Holland) Education Committee—The Director of Education, High Street, Spalding. An assistant in the development section of the British Non-Ferrous Metals Research Association—The Director, British Non-Ferrous Metals Research Association, Regnart Buildings, Euston Street, N.W.1. An engineering draughtsman under the Air Ministry—The Secretary (S.1), Air Ministry, Kingsway, W.C.2.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Magnetic Experiments on the Cosmic Rays.

BOTHE and Kolhörster [1] were the first to show that the cosmic rays manifest themselves to us as highly penetrating corpuscular rays. Direct experimental data on the nature as well as on the energy of these rays are still lacking; they might be obtained by experiments on the magnetic deflection if a sufficiently large and intense magnetic field could be reached.

I have attempted to overcome the difficulty of producing such a field by making use of the magnetic induction in a mass of magnetised iron.[2] Some preliminary experiments using the method of triple coincidences between the impulses of three Geiger-Müller tube-counters to define and analyse the beam of corpuscular rays, only show that these rays are not deflected in iron to an extent comparable to the deflection which electrons of 10^8 *e*-volt would be subjected to. The experiment was repeated later by Mott-Smith,[3] with the same method but with greater precision; the results were again negative and the energy of the corpuscular radiation, presumed to be electronic, was given as 2×10^9 *e*-volt as an approximate minimum value.

A fresh and more extensive series of measurements of the deflection of the corpuscular rays in magnetised iron have been recently undertaken by me, using an improved and more sensitive arrangement (which has already been briefly described[4]) on a principle suggested by Prof. Pucciante.

Figs. 1 and 2 represent the apparatus used in a first experiment in plan and in vertical section. The core of the magnet consists of two iron plates *A* and *B*, 2·8 cm. × 13 cm. × 38 cm., four millimetres apart; the two armatures *C* and *D* close the magnetic circuit. The wire carrying the magnetising current is wound round the plates in a single layer of seven turns per centimetre; with a current of five amperes the induction field inside the iron (measured with a ballistic galvanometer) is 16,200 gauss; the induction lines are closed without emerging from the core, and pass through it, as indicated by the arrows, clockwise or counter-clockwise according to the direction of the magnetising current. Above and below the magnet are two tube counters, each of 2·5 cm. internal diameter and of an effective length of 25 cm.; their axes are horizontal and parallel to the direction of magnetisation.

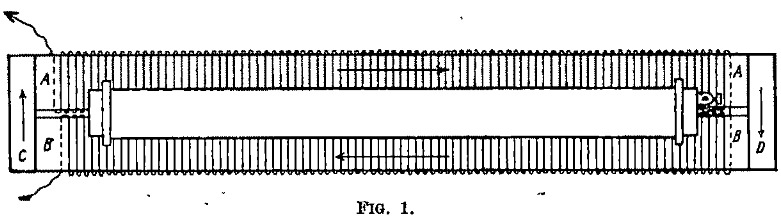

FIG. 1.

The experiment was carried out by counting the coincidences between the impulses of the two counters, alternately reversing the direction of the magnetising current. Since the two plates are inversely magnetised, the corpuscles are deflected in contrary directions, according as they pass through the first or the second plate. It is consequently easily seen that the corpuscles which have passed through the first counter (if negatively charged) are concentrated in the second or are repelled from it according as the induction lines are counter-clockwise or clockwise. An increase in the frequency of the coincidences in the former case and a diminution in the latter is therefore to be expected. If the corpuscles are positively charged, the conditions are reversed.

Perhaps the performance of the apparatus will be better understood by explaining that the effect of magnetising the plates is to alter the angular aperture of the beam subtended by the lower counter from any point of the upper (see Fig. 2). The effect which may be expected from a beam of corpuscles all of the same energy can be represented approximately (provided *R* is not too small and the loss of energy in the iron is neglected) by the formula: $\frac{\Delta N}{N_0} = \frac{140}{R}$, where *R* is the radius of curvature of the path of the corpuscles which penetrate the plate perpendicularly to the induction lines, N_0 is the frequency of the coincidences when the field is zero, ΔN is the difference between the frequency of the coincidences with the field in alternate directions. For electrons or protons of 10^{10} *e*-volt the above formula gives, for example, $\frac{\Delta N}{N_0} = 0{\cdot}068$.

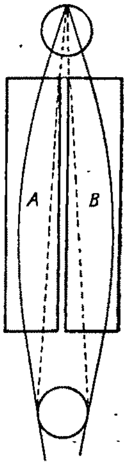

FIG. 2.

The result of the measurements was as follows:

Field clockwise:
In 197h 34m . . . 21·534 coincidences.
Field counter-clockwise:
In 197h 34m . . . 20·756 coincidences.

$$\Delta N = 778 \pm 200 \quad \frac{\Delta N}{N_0} = \frac{778 \pm 200}{\frac{1}{2}(21{\cdot}534 + 20{\cdot}756)} = 0{\cdot}037 \pm 0{\cdot}01.$$

(The chance coincidences, amounting to 1205 for each series of measurements, have been deducted from the above figures.) The difference is therefore 3·7 times greater than the mean error, and it may be considered as being very probably true. It will be noted that its sign is that proper to a beam of positive particles.

In order to test whether this effect was actually due to the deflection of the penetrating corpuscular rays, which pass through the iron, the experiment was repeated with a magnet similar to the former, but of greater size. If the above assumption is correct, an effect three times larger was to be expected. The result of the measurement was as follows:

Field clockwise:
In 108h 9m . . . 5·261 coincidences.
Field counter-clockwise:
In 108h 9m . . . 5·157 coincidences.

$$\Delta N = 104 \pm 105 \quad \frac{\Delta N}{N_0} = \frac{104 \pm 105}{\frac{1}{2}(5261 + 5157)} = 0{\cdot}02 \pm 0{\cdot}02.$$

It is seen that the difference is within the limit of the experimental error (twice as great as in the former experiment) and does certainly not reach the expected value. The little effect found in both experiments may be due to the deflection of positive secondary particles of lower energy, generated inside the iron. Safely, however, one can only say that the primary corpuscular rays are not deflected, by passing through the iron to such a great extent, as electrons or protons of 10 or 20 milliards *e*-volt would be, provided the effective magnetic field is identical with the induction field. (In the latter experiment, for example, it was from electrons of 10^{10} *e*-volt that an effect of 20 per cent was to be expected.)

A fuller description of the experiments, with a more exhaustive discussion of the results obtained, will be published later.

Nuclear Moments of the Isotopes of Lead: Relative Values of the $g(I)$ Factors of Pb(207) and Tl.

As a continuation of the programme that was initiated with the analysis of the hyperfine structure of Tl II,[1] the hyperfine structure of Pb III was investigated. The important Pb III lines [2] in the visible region were examined by means of a concave and an echelon grating. The structure and intensities of the patterns were interpreted consistently by attributing $I=0$ to the two even isotopes Pb(206) and Pb(208), and $I=\frac{1}{2}$ to the odd isotope Pb(207). This interpretation is in agreement with Kopfermann's[3] deductions based on the structure of Pb I and II lines and with Schüler and Keyston's[4] inference based on intensity measurements of the lead line λ4058.

The observed H.F.S. of Pb(207) III is similar in regard to relative separations to that of Tl II. The magnitudes of the separations in Pb(207) III, however, are much smaller than those of Tl II. The separation of the $6s7s'\ {}^3S_1$ of Pb(207) III is only 2·25 cm.$^{-1}$ as compared with the 4·97 cm.$^{-1}$ separation of the corresponding state of Tl II.

From these separations of the ${}^3S_1$ states of the two spectra, the values of the interaction constants of the $6s$ electrons of the $6s7s$ configurations of Pb(207) III and Tl II can be evaluated.[5] A comparison of these values shows that the $g(I)$ factor of the Tl nucleus is about four times that of the Pb(207) nucleus.

This result is especially significant. Up to the present the observed I values have been explained consistently on the assumption that only spinning protons contribute to the resultant moment of the nucleus.[6] The simple assumption that each proton contributes $\frac{1}{2}h/2\pi$ to the resultant was sufficient to explain the known facts. On this simple theory, the resultant moments of the nuclei of Tl and Pb(207), for both of which $I=\frac{1}{2}$, would be due to one unneutralised spinning proton. The $g(I)$ factors of the two nuclei, then, would be expected to be the same, since there is no evidence to indicate why different spinning protons with the same mechanical moments should have widely different magnetic moments. Contrary to this expectation, experiment shows that the $g(I)$ of the Tl nucleus is about four times that of the Pb(207) nucleus. The obvious conclusion is that the moment of at least one of the nuclei is composite and not due simply to a spinning proton. This conclusion invalidates the simple rule that each proton contributes $\pm\frac{1}{2}h/2\pi$ to the resultant, and necessitates endowing some of the protons in at least one of the nuclei with some property in addition to spin.

Our knowledge of extra-nuclear electronic structure suggests orbital motion. This model is not extreme, since the dimensions of a proton relative to a complete nucleus are of the same order as the dimensions of an electron to the atom. Such a model has the possibilities of explaining not only resultant I values, but also the nuclear $g(I)$ factors, even if the latter are negative.

Diamagnetism of Liquid Mixtures.

WITH regard to the discussion in NATURE by Trew and Spencer[1] and Ranganadham[2] on the diamagnetism of liquid mixtures, I should like to communicate the following data based on measurements carried out by me.

I find that the deviations from the susceptibility for the mixture calculated from the proportions of the components for acetone-chloroform is only 2 per cent. I find no trace of paramagnetism. Trew and Spencer believe that the paramagnetism they find for this mixture is probably attributable to the formation of dimethyltrichloromethyl carbinol (in German, Trichlorbutylalkohol tertiär), which their measurements show to be *paramagnetic*. I find this substance to be *diamagnetic* ($\chi=-0{\cdot}65\times10^{-6}$, and with water of crystallisation present $\chi=-0\ 67\times10^{-6}$). Further, for this substance I have obtained values of $\chi=-0{\cdot}64_5$ and $\chi=-0{\cdot}66\times10^{-6}$ respectively from calculation following Pascal's rule. Again, the density of this substance according to Trew and Spencer is 0·66, whereas I find it to be 1·5, and these authors state that the substance is pale yellow, while all chemical references agree that it is white, a fact which I have observed myself. I find in agreement with previous work that the melting-point is 96·5° C. (97° C.?) and 76° C. in the case where water of crystallisation is present. Two samples of dimethyltrichloromethyl carbinol where investigated, one from Kahlbaum, the other made by Frl. Karin Meyer; the two showed identical properties.

The capillary ascension method of Quincke was employed using field strengths of 8200, 3850, 1800, and 1300 gauss; the last of these gave only qualitative results since the sensibility at this field strength was not sufficiently great. In view of the present results, the possibility of explaining Trew and Spencer's measurements (at 640 gauss) by an anomalous dependence on the field strength is thus probably excluded. For the dimethyltrichloromethyl carbinol a Weiss (bifilar) balance method was employed to determine the susceptibility using a field of 8500 gauss.

It should also be noticed that the density curve for acetone and chloroform, given by Trew and Spencer in their original paper, shows that dimethyltrichloromethyl carbinol could not have been present in this mixture, for if it had been, a large density anomaly would have appeared.

The use of Pascal's theoretical values, by means of which Trew and Spencer have attempted to support their results, appears to me to be misleading. For example, the single exception in agreement between theory and measurements quoted by Trew and Spencer, namely, acetone, is precisely the substance for which the large deviations are found to occur. Further, a closer inspection of Pascal's results shows that the deviations between calculated values and experimental observations of other authors are systematic, that is, the greater the halogen (Cl, Br) content of a compound the greater these deviations become.[3] My results, $\chi = -0{\cdot}58 \times 10^{-6}$ for acetone and $\chi = -0{\cdot}485 \times 10^{-6}$ for chloroform, are within the limit of error of previous measurements recorded by other authors.

Function of Water Vapour in the Dissociation of a Salt Hydrate.

IN measuring the influence of the gaseous product upon the velocity of dissociations of the type

$$\text{Solid}_1 \longrightarrow \text{Solid}_2 + \text{Gas},$$

we have found an interesting effect with the reaction:

$$MnC_2O_4.2H_2O \longrightarrow MnC_2O_4 + H_2O,$$

which goes on slowly in a vacuum at 76°, at which temperature the dissociation pressure is approximately 135 mm.

The reaction rate under otherwise constant conditions is sensitive to quite small concentrations of water vapour. Plotted against a linear scale of water vapour pressures, the quotient

$$\frac{\text{Rate in vacuum}}{\text{Rate at } pH_2O}$$

(shown in the diagram as 'rate') at first falls sharply; this appears to be the normal behaviour of salt hydrates. But with increasing water vapour pressures the rate passes through a minimum at about 10^{-1} mm. (that is $<10^{-3}$ of the dissociation pressure) and then rises, to pass through a maximum of the same order as the rate in vacuum; thereafter it falls again along a more gentle curve eventually to zero at the dissociation pressure. So far as we know at present, this minimum and maximum is a unique case.

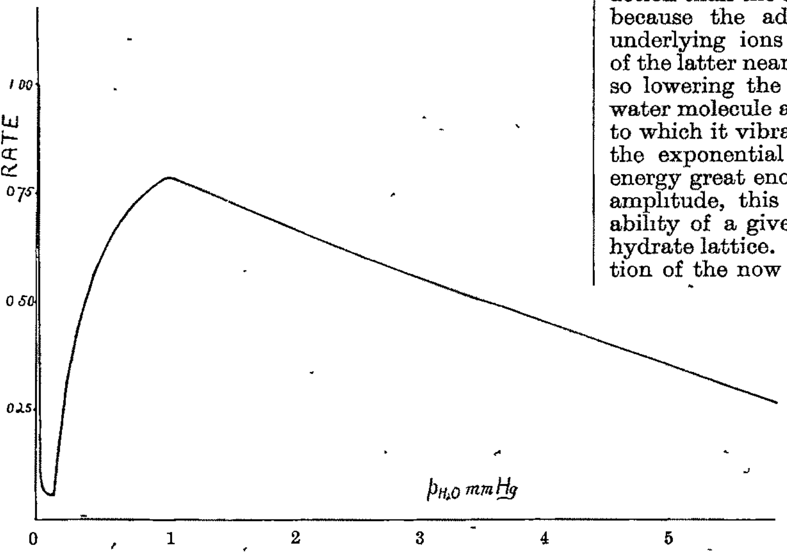

FIG. 1.

In rough outline the following picture might provide a qualitative explanation of the effect: the reaction is experimentally of the usual 'interface' type, that is, dependent upon the presence of the anhydrous phase. It possesses a large temperature coefficient, so that the rate-governing process is subject to a considerable activation, presumably in vibrational degrees of freedom. In our view, two stages are involved:

$$\text{Salt hydrate} \rightleftarrows (\text{Anhydrous salt} + H_2O \text{ adsorbed in interface}) \rightleftarrows \text{Anhydrous salt} + H_2O \text{ (gas)}.$$

Water molecules in the hydrate lattice adjoining the anhydrous phase require a smaller vibrational energy to enable them to break out of the lattice because of the attraction exerted by the ions on the opposite side of the reaction zone; hence the reluctance of the reaction to take place in the absence of the second solid phase.

Water vapour in the gas phase establishes an adsorption equilibrium in the interface zone between the two solids rapidly in comparison with the slow chemical reaction. The net rate of decomposition is now decreased (*a*) because it is the difference between two opposing rates, (*b*) because a fraction of the interface is blocked for decomposition by the adsorbed molecules already present.

As the two-dimensional density of adsorbed molecules increases (with the arbitrarily maintained partial pressure) a stage will be reached in which the gaps in the adsorption layer are more or less surrounded by other adsorbed molecules. We suppose that these gaps may be much more effective in promoting the reaction than the corresponding area not so surrounded, because the adsorbed molecules polarised by the underlying ions virtually carry the attractive field of the latter nearer to the hydrate side of the interface, so lowering the force constant between the hydrate water molecule and the rest of its lattice, with respect to which it vibrates in the reaction zone. Because of the exponential factor governing the chance of an energy great enough to give the molecule an assigned amplitude, this may increase enormously the probability of a given molecule breaking loose from the hydrate lattice. At the same time, the mutual attraction of the now rather numerous adsorbed molecules polarised by oppositely charged ions will decrease the probability of a given molecule contributing to the reverse reaction by passing from the adsorbed layer back to the lattice. The combined effect is to cause the net rate to rise again, and clearly it must pass through a maximum and fall again more slowly as the gaps available for the forward reaction become filled up and the number of molecules in a position to contribute to the reverse reaction is still further increased. Ultimately the two opposing rates become equal at the dissociation pressure.

The initial rapid fall with very small fractions of the dissociation pressure explains the well-known difficulty of approaching the equilibrium in many salt hydrate systems experimentally.

Magnetism of Colloidal Gold.

IN three previous notes in NATURE[1] it has been pointed out that the diamagnetism of graphite, antimony, and bismuth decreases with particle size. This was most striking in graphite and less in antimony and bismuth. In a later communication on the same subject[2] I adopted two methods of colloidalisation of bismuth—Bredig's method and mechanical colloidalisation. In Bredig's method I obtained an abnormally low value, due to the powder containing a mixture of oxide and the metal, as was pointed out by me. In the case of bismuth, S. S. Bhatnagar[3] contends that he obtains a large amount of oxide by mechanically colloidalising bismuth, and part of the decrease of diamagnetism that I obtained by that method is also due to oxidation.

We have recently investigated carefully prepared gold sols avoiding all possibilities of oxidation. The sol was prepared by the method of Zsigmondy for the preparation of gold sols, by reducing dilute solutions of gold chloride ($HAuCl_4$) by formaldehyde. The particle sizes are 10-40 $\mu\mu$ as mentioned by him. The sol was always kept in an atmosphere of hydrogen and never allowed to come in contact with the atmosphere. It was coagulated, washed, and dried in a high vacuum desiccator. From a large quantity of the sol about 20 mgm. were obtained as precipitate.

Its susceptibility was then determined in a high sensitivity Curie balance, the substance being sealed in a thin capsule and a correction being applied for the susceptibility of the latter. The specific susceptibility, χ, obtained was $0{\cdot}0804 \times 10^{-6}$, the value for gold in the massive state being $0{\cdot}15 \times 10^{-6}$ (I.C.T.).

As Gerlach has explained[4] the phenomena observed by Honda[5] on the decrease of diamagnetic susceptibility of copper and silver on cold working as due to the small percentages of the amorphous substance dispersed in the main body of the elements, it is possible that in a sol a very small percentage is in an amorphous state. An alternative suggestion is that a small percentage is in a crystalline structure different from cubical (copper, silver, and gold are cubical in structure), as the sols of gold and silver are known to exhibit magnetic double refraction. The well-known X-ray spectrograms of colloidal gold and that of crystals by Debye and Scherrer, however, show that both give similar line spectra, but in the former case the lines are more diffuse. While more work is necessary to decide completely between these explanations, it is certain that diamagnetism in gold and possibly also in many other substances depends on crystalline and block structure.

Structure of the Trifluorides of Aluminium, Iron, Cobalt, Rhodium, and Palladium.

UNTIL recently very little was known about the structure of these trifluorides.[1,2] An examination by the powder method was made of aluminium and iron trifluorides, forming a part of an investigation on the structure of the trihalogen salts of aluminium, iron, and chromium. The diagrams so obtained proved that the trifluorides mentioned in the title are all isomorphous, as was already known of the four latter compounds.

The hexagonal elementary cell contains three molecules:

AlF_3 : $a = 4{\cdot}93$ A., $c = 6{\cdot}25$ A., $c/a = 1{\cdot}265$
FeF_3 : $a = 5{\cdot}20$ A., $c = 6{\cdot}66$ A., $c/a = 1{\cdot}28$ [2]
CoF_3 : $a = 5{\cdot}06$ A., $c = 6{\cdot}63$ A., $c/a = 1{\cdot}31$ [2]
RhF_3 : $a = 4{\cdot}88$ A., $c = 6{\cdot}81$ A., $c/a = 1{\cdot}39$ [2]
PdF_3 : $a = 5{\cdot}05$ A., $c = 7{\cdot}08$ A., $c/a = 1{\cdot}40$ [2]

Contrary to Ebert,[2] I found that these structures are not purely rhombohedral, for with chromium *Kα* rays it was possible to discern undoubtedly 200 near 003 (111 rhombohedral). The space group proved to be D_3^1 with metal on

one onefold position : 000, and on
one twofold position : $\frac{1}{3}\,\frac{2}{3}\,u_1$; $\frac{2}{3}\,\frac{1}{3}\,\bar{u}_1$; with $u_1 = \frac{2}{3}$.

The fluorine ions on :

(1) one threefold position :

$$u_2\,u_2\,\tfrac{1}{2} \;;\; 0\,\bar{u}_2\,\tfrac{1}{2} \;;\; \bar{u}_2\,0\,\tfrac{1}{2} \;;\; \text{with } u_2 = \tfrac{2}{3},$$

(2) one sixfold position :

$$xyz \;;\; y - x,\ \bar{x},\ z \;;\; \bar{y},\ x - y,\ z \;;$$
$$yx\bar{z} \;;\; \bar{x},\ y - x,\ \bar{z} \;;\; x - y,\ \bar{y},\ \bar{z},$$

with $x = \frac{1}{6}$, $y = \frac{5}{6}$. $z = \frac{1}{6}$.

These five parameters will differ very little from the above rational values. The intensities calculated with these parameters are in good agreement with those observed.

In the case of aluminium trifluoride, u_1 is perhaps 0·70 rather than $\frac{2}{3}$.

The structure consists of alternating planes of metal and fluorine ions, the latter being close-packed around the first.

The distance between two fluorine ions is somewhat smaller than that calculated with a radius of 1·33 A., namely: $AlF_3 = 2{\cdot}46$ A., $FeF_3 = 2{\cdot}60$ A., $CoF_3 = 2{\cdot}53$ A., $RhF_3 = 2{\cdot}44$ A., $PdF_3 = 2{\cdot}52$ A. This is in remarkable agreement with the observation in some trifluorides of the rare earths by Oftedahl,[3] who found 2·47 A. in lanthanum trifluoride.

The metal ions are arranged on a nearly cubic rhombohedron, the fluorine ions (2) are on the middle of the six polar edges; only the fluorine ions (1) are not on the middle of the other edges.

A full report will be given in the *Z. für Kristallographie*. A communication on the various structure types for compounds of the type MF_3 will also follow. I am indebted to Dr. H. J. Verweel for a part of the experimental work.

Effects of Inadequate Feeding on Insect Metamorphosis.

SOME years ago H. S. Pruthi pointed out[1,2] that moulting in insects is not the result of growth, but is "primarily concerned with metabolism". He found that intermittent starvation of the larvæ of *Tenebrio molitor* extended the duration of the larval period and increased the number of moults, the size and weight before pupation of the older larvæ being the same as in the younger ones. Partially starved larvæ of *Pieris brassicæ* also showed an increased number of moults, the size and weight before pupation being the same as in normally fed caterpillars used for control experiments. Pruthi therefore concluded that if "moulting is simply to allow growth, there is absolutely no necessity for extra moults", and expressed the opinion, based on observations detailed in his paper,[1] that if larvæ are starved before the commencement of the metamorphic processes pupation is delayed, while if they are starved after maturity pupation is accelerated. On the other hand, as he himself shows, several workers contradict the theory that inadequate feeding, quantitatively or qualitatively, delays metamorphosis.

My own limited experience supports those who take this view. In the case of *Orgyia turbata* Butler (Corbett and Dover[3]), on which observations were made by the Government Entomologist, F.M.S. and S.S., and his staff, it was found that a heavy mortality occurred among caterpillars fed on *Crotolaria* (a plant to which they were not accustomed), but that those which survived completed the larval period sooner and with less moults than those fed on *Mimosa*, the favourite food-plant of the earlier instars. It seems, therefore, that diminished metabolic activity, consequent on an unpalatable food-supply, accelerates the completion of the larval period, probably because there is a lesser accumulation of waste nitrogenous and carbonaceous matter, the elimination of which, as suggested by Eisig and Sharp[4], is assisted by ecdyses. Moreover, "a quick life-cycle would increase the possibility of the larvæ surviving the disadvantages occasioned by unhealthy food". These opinions are of interest, not only because they partially contradict the views of Pruthi and others (while supporting the fundamental hypothesis that moulting is more intimately connected with general metabolism rather than with growth), but also because they suggest that "an insect which has once gained a foothold on a plant which is commonly supposed to be unpalatable may be more numerous than on more favoured food-plants", at least during the initial stages of adaptation.

How can the difference between the above observations and those of Pruthi be explained? The answer probably lies in the fact that in all his partial starvation experiments starvation was intermittent, while in the case of *Orgyia turbata* fed on *Crotolaria* the food-supply was apparently unpalatable, and was not partaken of so freely as was *Mimosa*: there was a reduction in the quantity of food taken, but there were no periods of starvation followed by normal feeding. The interpretation of Pruthi's results, therefore, appears to be that a comparatively lengthy period of starvation, followed by an equal period of normal feeding, disturbed the metabolic rhythm to the extent of retarding growth. The increased number of moults observed in his intermittently starved larvæ can be explained by Eisig and Sharp's theory, for the nature of the feeding permitted to them must have resulted in an excessive accumulation of waste products which ecdyses helped to eliminate. If these explanations are accepted, it will be seen that Pruthi's results are brought more into line with the proposition that, in many cases, an unpalatable and reduced food-supply accelerates the completion of the larval period. The problem is, however, a controversial one, and is of both biologic and economic interest. Further investigations should therefore be of value.

Excitation of the Green Auroral Line.

THIS note will be of special interest when compared with my paper on the light of the night sky, published in a recent number of the *Physical Review*, and with my report before the Pasadena meeting of the American Physical Society, in which I reported the first effectively complete reproduction of the aurora spectrum. On many of the spectra which were photographed during the progress of the above-mentioned experiments, it was thought that there were definite, though weak, indications of the presence of the green auroral line. The failure of the green line to appear with considerable intensity in these experiments was never considered to be serious, since there was ample evidence for the occurrence of collisions between excited nitrogen molecules and metastable oxygen atoms in the states which are involved in the emission of the green line. Since the state on which the green line originates is metastable, it is not at all surprising that the line was either absent or missing in these experiments.

In my most recent experiments, on raising the pressure from 10^{-3} mm. to about 5 mm. by admitting oxygen to the tube in which the auroral spectrum was reproduced at the lower pressure, it was found that, so far as the excitation of oxygen was concerned, the tube behaved very much as it did at the lower pressure. Now at 10^{-3} mm. it was often possible to obtain a large decomposition of oxygen molecules into atoms, without the appearance, however, of the arc spectrum of oxygen. The presence of atoms in great numbers was indicated by the incandescence of small bits of oxide (as in atomic hydrogen) and also by strong heating of small patches of the tube wall. Now the production of oxygen atoms, under conditions where no arc lines (other than the green line) are produced, arises both in the aurora and in the night sky. Because of the marked resemblance between the low-pressure tube and the high-pressure tube, a photograph was taken of the spectrum of the high-pressure tube and a fairly strong excitation of the green line was observed. Other plates showed that when the arc lines of oxygen increased in intensity the green line decreased in intensity, which indicates that the process by which the green line is excited in these experiments is one which does not excite the arc spectrum. Such a process is discussed in some detail in my paper on the light of the night sky.

It is believed that the process of excitation of the green lines is the same in both the high-pressure and the low-pressure tubes, but that at high pressures the green line is emitted because collisions with the wall or with nitrogen molecules are less probable in view of the diluting effect of the added oxygen. It is also possible that the lifetime of the metastable oxygen atom which emits the green line is less at high pressures than at very low pressures in view of the close proximity of excited atoms and molecules.

It is important to note that the green line was excited in the present experiments without the use of rare gases. Practically all other laboratory reproductions of the green line have been made with the help of rare gases. Fuller discussion of the present work will show that the present excitation of the green line and the rest of the auroral spectrum is probably the one that occurs in Nature, and furthermore, it is a phenomenon in which only oxygen and nitrogen are involved. For that reason the present experiments should have a direct bearing on the problem of the origin of auroral displays.

The Slow Combustion of Methane and Ethane.

THE observations referred to by Prof. W. A. Bone in NATURE of Aug. 1 (p. 188) with regard to the source of alcohols in the combustion products of paraffin hydrocarbons were based on experimental evidence accumulated in Great Britain and other countries from the point of view of the peroxide mechanism of combustion; compare, for example, in the case of methane, the work of Wartenburg and Sieg,[1] who concluded that methane first forms the moloxide $CH_4(O_2)$. It is interesting to note that the earlier supporters of the peroxide theory of oxidation had discovered the presence of alcohols in the oxidation products of hydrocarbons, but it was considered that these alcohols had been derived directly from the peroxides or from the esters[2] and not at all from a primary hydroxylation process.

The particular view that oxygen first enters the –CH group with its labile hydrogen, to form an alkyl hydrogen peroxide, was arrived at in 1926, after a consideration of the results obtained in a research on the slow oxidation of a large number of fuel vapours in air.[3] Attempts to isolate organic peroxides were unsuccessful,[4] but now, after five years, it has been discovered by Dumanois, Mondain-Monval, and Quanquin that alkyl hydrogen peroxides are present, not only in the combustion tube, but also in the petrol engine.[5]

An intensive study of the oxidation of ethane and methane in air with and without the addition of inhibitors, carried out by myself (an account of which has been submitted for publication), has provided further evidence in favour of the Engler-Bach peroxidation theory of combustion. The experiment of endeavouring to isolate the moloxide or the activated methyl hydrogen peroxide from methane has not been attempted, since it is considered that at the temperatures of the experiment, namely, above 600° C., any organic peroxide would have an extremely short life, and if any organic peroxide were isolated, then, as Staudinger points out, it would not be the primary one, but a derivative or degraded form of it. The peroxidation theory of combustion is not essentially based on the isolation and identification of organic peroxides, but rather on the characteristic behaviour of inhibitors and surfaces and on the phenomena of autoxidation and autocatalysis.

It would be interesting to know how Prof. Bone would explain by the hydroxylation theory the autoxidation of benzene vapour to phenol or of aniline vapour to tars at low temperatures, facts recorded in the literature of hydrocarbon combustion.[6]

Œstrus-Producing Hormones.

RECENTLY, Doisy and his co-workers (1931) have reported the isolation from the urine of pregnancy of a crystalline substance possessing œstrus-producing activity, which is distinct from the active substance theelin, previously described by them. The latter substance, to which they gave the formula $C_{18}H_{21}(OH)_2$, was shortly afterwards isolated by one of us (Butenandt, 1929)[1] and by Dingemanse and co-workers[2] (1930). It was shown afterwards (Butenandt, 1930) that this substance is represented by the formula $C_{18}H_{22}O_2$, and that it behaves either as a hydroxy ketone or as a dihydroxy alcohol.

There is no doubt that the second substance isolated by Doisy and his co-workers,[3] to which they give the formula $C_{18}H_{21}(OH)_3$, is identical with that fully described earlier by one of us (Marrian. 1930)[4]. Although Prof. Doisy refers to the triol previously isolated, there is no suggestion in his papers that it had been characterised as a trihydroxy substance of the formula $C_{18}H_{21}(OH)_3$. His view that the substance described by one of us is a mixture of both active substances is apparently based solely on a difference between the *uncorrected* melting points. The evidence of the analytical data, which clearly shows this supposition to be untenable, is ignored.

A year ago when the presence in urine of two distinct œstrin-producing substances was clear to us, we were considerably puzzled over the relationship between them. The suggestion was tentatively advanced (Marrian, 1930) that the substance $C_{18}H_{22}O_2$ on treatment with hot alkali took up the elements of water to form $C_{18}H_{24}O_3$. This supposition was afterwards shown to be incorrect (Butenandt, 1930), since the former substance proved to be unchanged by such treatment. At the same time it was shown that both substances occur together in urine, and that by distillation in a high vacuum with potassium bisulphate, $C_{18}H_{24}O_3$ could be converted into $C_{18}H_{22}O_2$. Prof. Doisy has made no adequate reference to this work, and has advanced the earlier view, which has been shown to be untenable.

Segregation of Floral Characters in the Wild Oxlip.

DR. C. J. BOND[1] finds that in hybrids between the primrose (*Primula vulgaris*) and the cowslip (*Primula veris*) the earliest flowers were formed singly on long peduncles of the primrose type, while the later ones were arranged in the umbelliferous type as in the cowslip. He asks whether these two types of inflorescence are also found in the true oxlip (*Primula elatior*).

I have cultivated this latter plant, originally obtained from Cambridgeshire, for many years, and have never seen any of the plants producing flowers singly on peduncles as in the primrose. They were always produced on a common erect scape. In Switzerland, too, where I found them last May, this was the sole method of flower-bearing. This fact, therefore, would support the more generally held opinion that *Primula elatior* Jacq. is a true species and quite distinct from the hybrid between the primrose and cowslip, from which it differs in other characters also.

In hybrids of my own raising, between the primrose and the true oxlip (*Primula elatior*), I have, however, often noticed the phenomenon described by Dr. Bond for hybrids between primrose and cowslip. I have also seen the two types of flower-bearing in hybrids which I have raised from *Primula elatior* crossed with *Primula Juliae*. In this case also the single pedunculate flowers preceded those borne on a common scape, which was usually comparatively short. It would appear, therefore, that in crossing some species of *Primula*, one of which produces its flowers singly and the other bearing numerous flowers on a common scape, neither type of inflorescence is completely dominant, but that both types may occur in succession. As this condition occurs also in the cultivated form known as Mrs. McGillivray, it would point to this plant being a hybrid, probably with *Primula Juliae* as one of the parents.

Research Items.

The Roman Neanderthal Skull.—A description of the Neanderthal skull found at Saccopastore, near Rome, as first announced to the Société romaine d'Anthropologie on June 1, 1929, is given by Prof. Sergio Sergi in *L'Anthropologie*, t. 41, Nos. 3-4. It is one of the best preserved of the Neanderthal skulls, and the condition of the base affords an exceptional opportunity of appreciating its characteristics. The cranial capacity is 1200 c.c., which makes it the smallest known of the Neanderthal skulls. This fact, combined with its refinement in character, suggests that it is the skull of a female, and, judging from the state of the sutures and dentition, it is that of a young woman. The position of the foramen, which is farther forward than in the Chapelle-aux-Saints skull, in which, however, the position may be due to faulty orientation and reconstruction, indicates that the head was carried as erect as in modern man. The cephalic index is approximately 78·4. The horizontal contours of the Saccopastore and La Chapelle skulls, taken in the plane of the lambda, coincide in a surprising manner. The horizontal perimeter is, at the maximum, 520 mm., La Quina being 515 mm. Near the lambda is a complex system of wormian bones, a common phenomenon in Neanderthal skulls. The significance of this feature has hitherto been overlooked; but it points to instability in the occipital region over the inion, which is here in course of evolution. In norma lateralis the whole peribregmatic region shows flattening, the frontal inclination (74°) and occipital (70·5°) being comparable to that of the Gibraltar skull. In a posterior segment the skull shows a certain degree of roundness, contrasting with the bun-like projection of the occiput in La Chapelle and La Quina. The face and its features are very large. In its general dimensions and its morphology the skull is nearest to the Gibraltar skull. The associated fauna point to a dating at the Riss-Würm Interglacial.

Milk Diets for Rats.—We have received the first number of the fourth volume of *The Journal of Nutrition* (Messrs. Baillière, Tindall, and Cox). This journal, which is produced in the United States, was started in 1929, and has established itself as a scientific periodical dealing with many different aspects of the nutrition of animals and human beings. Among the original contributions are papers by J. Waddell, H. Steenbock, and E. B. Hart on the effects of milk diets on rats. On whole cow's milk supplemented with copper the animals suffered from anæmia, and growth and reproduction were subnormal although third-generation animals were secured. When iron was also added to the diet, no anæmia occurred, but growth and reproduction were still subnormal. The females matured late and the reproductive cycles were prolonged. Small amounts of manganese or iron improved the ovulation rhythm. No evidence of lack of vitamin E was observed. The males suffered from testicular degeneration, which also was not due to deficiency of vitamin E. It was also found that addition of iron to an ordinary stock ration prevented the animals from utilising the vitamin E in the diet or possibly destroyed its vitamin E content. D. L. Hussemann and R. A. Hetler found that vitamin B_2 is probably more essential for successful lactation in the rat than vitamin B_1, although both are required.

Incubation of the Mexican Jacana.—The share taken by the respective parents in the incubation of the eggs of shore-birds still requires much investigation. Alden H. Miller contributes new facts concerning the breeding activities of the Mexican jacana (*Jacana spinosa*) observed at Lake Olomega, Central America (*Condor*, vol. 33, p. 32; 1931). Scrutiny of the marsh at a distance of 50-75 yards revealed the presence of nests, which were betrayed when the adult birds quietly ran or sneaked away. In every case it was the male bird which was flushed from the nest, and although in some instances the females were near by, they were little disturbed by an intruder at the nest, in contradistinction to the males. It is the author's impression that females were more often seen about nests containing fresh or slightly incubated eggs than about eggs heavily incubated or where there were young. He decides that the male jacana performs most if not all of the incubation, and that it also cares for the young. Females take relatively little interest in eggs and young, although they are decidedly active in courtship. Another interesting observation was that the demonstrations indulged in by the incubating birds were much less frantic than the demonstrations of birds accompanied by young, and that 'broken wing' antics were seen only in cases where the eggs were hatching or where young were following the male parent.

Nitrogenous Excretion in Invertebrates.—Prof. H. Delaunay contributes to *Biological Reviews* (Camb. Phil. Soc., vol. 6, July 1931) a useful summary of recent work on excretion in invertebrates. He directs attention to the three main types of excretory organs —(*a*) those which open to the exterior, for example, nephridia, malpighian tubes of insects; (*b*) those in which excretory substance accumulates, for example, the branchial heart of cephalopods; (*c*) the atrocytic organs or cells which shed into the fluid in some cavity the solid or liquid which they produce, for example, the chloragogen cells of oligochætes, the pericardial cells of insects. An account follows of recent observations on excretion, beginning with the Protozoa. In *Paramecium* and *Spirostomum* nitrogen is excreted as urea, but in *Didinium* in ammoniacal form. In *Spirostomum*, the fluid withdrawn by means of a micropipette from the contractile vacuoles contains so small an amount of urea that it would appear that these vacuoles serve simply to expel the excess of water from the cytoplasm, and that the nitrogenous waste passes out by osmosis from the entire surface of the organism. In leeches, ammoniacal nitrogen forms the major part of the excretion, and this appears to be true also for earthworms. The absence of uric acid in the concretions and extracts of nephridia appears to be general (but Willem has stated that in the concretions in the excretory organs of *Arenicola* urate of sodium is present). On the contrary, uric acid preponderates in the excretory material of insects. The author reviews the conditions in cœlenterates, sponges, echinoderms, molluscs, crustacea, insects, and araneids, and then passes to a comparative study of the different nitrogenous excretory products.

Methylene Blue Stain for Yeast Cells.—The hitherto unsuspected factors producing anomalous results in the staining of yeast cells with methylene blue have already been indicated in Nature (**126**, 491; 1930), and the necessity for revision of the technique is further demonstrated by the work of Fink and Weinfurtner, recorded in the *Wochenschrift für Brauerei* (48, 159; 1931). Portions of a 0·4 per cent suspension in distilled water of fresh pressed yeast were added to five times the volume of solutions of certain sugars. It was shown by plate-culture experiments that, after 30 minutes, most of the cells were still alive, although the methylene blue test indicated that only 10 per cent had survived compared with 95 per cent in a blank experiment. It is clear that in order to take the stain so readily the permeability of the walls of the yeast cell must have undergone a considerable increase in excess of that which normally occurs when yeast is suspended in distilled water. This increase is attributed to the sugar used, cane sugar, dextrose, lævulose, and galactose being approximately equal in effect, whilst maltose produces a smaller increase in permeability. The increase seems to be related to the fact that the sugars are non-electrolytes, since addition of potassium chloride in 0·1 *N* strength inhibited it completely: that is, the original impermeability of the walls was restored, the living cells being less susceptible to the stain than the dead cells. Revision of technique, therefore, will have to allow not only for the *p*H value of the medium, but also for the fact that in the absence of electrolytes and in the presence of sugars methylene blue will readily enter the cell and afterwards inhibit its growth.

Germination of Damaged Seeds.—How much a seed can be damaged without seriously affecting the resulting plant has been a matter of controversy since the inception of seed testing, and the question has been recently investigated by the British Association of Commercial Seed Analysts. New seed of species of *Brassica* may be damaged in a variety of ways; the testa may be lost or cracked, or the seed may be partially sprouted or attacked by weevils, and yet show a germination of seventy-five to a hundred per cent. Yearling seed, however, gave less satisfactory results. In the case of timothy, although badly damaged seed was of little value, that which was only slightly eaten showed a fifty-six per cent germination, and it seems possible that a satisfactory line of demarcation may be drawn between good and useless seed. As regards leguminous seeds, lucerne is the least susceptible to damage, more than eighty per cent germination being recorded, except in those cases where fracture had occurred at the junction of the cotyledons and radicle. Trefoil, alsike, and white clover, with seeds damaged in a similar manner, gave distinctly lower germination. The most striking results, however, were obtained with maple peas, even severely damaged seeds giving a seventy-eight per cent germination, of which fifty-six yielded mature plants. Soil tests carried out with new swede seeds, the testas of which were either entirely or partially missing, showed even up to ninety-seven per cent germination, failure only occurring where injury to the radicle was excessive. It would seem, therefore, that some revision in the use of the term 'impurities' in the case of such seeds is necessary.

Granites of Eastern Australia.—A valuable summary of the ages, distribution, and petrological characters of the granites of eastern Australia has been published by Prof. E. W. Skeats in the *Proc. Roy. Soc. Victoria*, 43, 1931, pp. 101-118. Pre-Cambrian granites appear to be limited to the western part of the area, thus lending support to the hypothesis that the growth of Australia has been, on the whole, from west to east. Cambrian intrusions are found in west Tasmania and central Victoria; those of the Lower Devonian are widespread from Tasmania to south New South Wales; those of the Upper Devonian range from Victoria to central New South Wales; Lower Carboniferous granites occur in Victoria and Queensland; and Permo-Carboniferous and Triassic (or post-Triassic) examples are found in north New South Wales and Queensland. The loci of granitic intrusion thus seem to have migrated northwards during the periods mentioned. Judged by the association of *lit-par-lit* intrusions with fluxion gneisses and highly folded and metamorphosed sediments, there were only two important periods of mountain-building, the first in the Pre-Cambrian and the second at a time doubtfully referred to the Lower Devonian. Most of the remaining granites are thought to have been intruded under conditions of tension.

Air Pollution at Pittsburgh.—A paper, from the *Pittsburgh Record* June–July 1931, by H. B. Meller, head of the Air Pollution Investigation of the Mellon Institute of Industrial Research, gives the results of a year's study of 'sootfall' in Pittsburgh, 1929–30, and comparisons with previous studies, 1912–13 and 1923–24. Within the period, Pittsburgh had increased its population from 534,000 in 1910 to 680,000 in 1930, with some 20 per cent increase of area. 'Sootfall' represents the deposit caught in 'containers' exposed in different parts of the city, eighteen in 1930, eleven on the previous occasions. They were changed monthly, and, in the last study, an additional set daily. The catch for the year ranged from 2319 tons per square mile at Woods Run to 553 at Mt. Washington. If the catchment is on the same lines as in the corresponding study in Great Britain, Mt. Washington would be rated as a *C* station and Woods Run as a treble *D*. The scheme of analysis is, however, not quite identical. In Pittsburgh deposits are classified into: combustible 36 per cent, ash 47, and iron oxide 17. British records count insoluble (tar, carbon or soot, and ash) 60 to 40 per cent and soluble (loss on ignition and ash) 40 to 60 per cent according to site, in town or country, and no special account is taken of iron oxide. Tar counts in Great Britain at about 1 per cent; at Pittsburgh 1·3 per cent at a railroad signal bridge and 5·1 per cent at a car-parking garage. In the conclusions, the triple problem is summarised as the elimination of smoke, dust, and sulphur; for the first two the solution is in sight, for the last "there is now no satisfactory process".

An Application of Thyratrons.—It is often necessary in radioactive work to count voltage pulses, such as those which are produced by amplifying the disturbances produced by single α-particles. Several circuits involving thyratrons which can be used for this purpose are described by Dr. Wynn-Williams in the July number of the *Proceedings of the Royal Society*. The thryatron is a grid-controlled arc tube, and has the property that a heavy anode current cannot flow so long as there are not merely thin positive ion sheaths on the grid wires. Essentially it is an inertialess relay system, with the relay action for starting controlled by the potential of the grid. Other means, such as interruption of the anode current mechanically, have to be employed to extinguish the arc current, and in earlier devices for counting with thyratrons, the speed of counting had been limited by the inertia of the extinguishing device. This difficulty is largely obviated on the circuits described in the present paper by using a number of thyratrons, so disposed that the lighting of the arc in one automatically puts another into a condition in which it is sensitive, and so gives the first a longer time to be reset by the mechanical quenching device without the recording system as a whole failing to record some of the pulses, if they follow one another rapidly. It has been found possible to record impulses separated by so little as 1/500 sec., and a system has been described, but not tested, in which the 'dial' recording numerically the total number of pulses is itself a system of thyratrons, containing no mechanical parts whatever.

Nitrogen Contents of Barley and its Wort.—The difficult task of summarising and interpreting the unfinished experiments of the late Prof. Schryver and of correlating the results of subsequent workers, including himself, has been ably accomplished by L. R. Bishop in a recent paper in the *Journal of the Institute of Brewing* (**37**, 345; 1931). The accumulated data provide some interesting generalisations. In particular, the soluble nitrogen compounds of a wort produced by mashing an English malt account for from 30 to 40 per cent of the total nitrogen present in the original dry barley, fluctuations in this proportion corresponding with variations in the conditions of malting and mashing. The temperature of mashing is of particular importance, and the methods recently devised for the determination of the various forms in which nitrogen may occur have enabled a distinction to be drawn between ammonia-, amide-, and amino-nitrogen, which remain almost constant in amount, and peptide-nitrogen, which is produced in maximum quantities by mashing at 50° C. It is interesting to note that the results confirm and amplify those obtained by H. T. Brown in 1909 in connexion with the relation of mashing-temperature and total permanently-soluble wort nitrogen. The wort carbohydrates also were shown to follow similar regular variations, the 'apparent maltose' giving a sharp maximum at 60° C., and dextrins and other constituents a less marked maximum at 70° C. These conclusions have a practical as well as a theoretical interest, since it is hoped that investigations at present in hand will show exactly which types of nitrogen compound best fulfil the feeding requirements of the yeast. When this link is supplied, a big step will have been taken towards deciding the optimum nitrogen content of the barley and predicting the best malting and mashing conditions.

Astronomical Topics.

New Bright Comet, 1931 *c*.—Mr. P. M. Ryves, who is a fellow of the Royal Astronomical Society and a member of the British Astronomical Association, residing at Zaragoza, Spain, telegraphed to the U.A.I. Bureau at Copenhagen that he had discovered a comet of magnitude 5·5 approaching the sun. The following positions of Aug. 10 and 12 (which are probably only approximate) were obtained by him; that of Aug. 14 was obtained by Prof. G. van Biesbroeck at Yerkes Observatory, after receiving the announcement of the discovery:

	U T	R A. 1931 0	N. Decl. 1931·0	Mag.
Aug.	$10^d\ 3^h\ 30^m$	$7^h\ 43^m\ 0^s$	23° 48′ 0″	—
,,	12 4 0	7 52 0	23 19 0	5·5
,,	14 9 29·1	8 4 32·53	22 45 46	4.0

The comet is visible in the morning twilight; an attempt was made to deduce an orbit from the above material, but the first two positions are probably not sufficiently exact for the purpose. The perihelion distance is likely to be small, and the comet may become visible in daylight, like the great comet of 1882 and Skjellerup's comet of 1927. Comets near the sun are difficult to observe, since the sky is too bright to see comparison stars. Positions obtained by reading the circles of equatorials are better than nothing.

Comets.—*Harvard Card*, No. 159, contains a suggestion from Mr. L. E. Cunningham that the comet recently detected by Herr Reinmuth on plates exposed on Mar. 4 and 5, 1902, is probably identical with comet 1925 II (Schwassmann-Wachmann 1). This is the remarkable comet the orbit of which lies wholly between those of Jupiter and Saturn. The daily motion accords exactly, while there is a discordance of 11^m in R.A., 1½° in Decl. These discordances are not unduly large, considering that the elements used were not definitive, and that the motion has been carried back twenty-five years, without applying perturbations. The comet would have been near aphelion in 1902, and as Reinmuth gave the magnitude as 12·0 it must then have been passing through one of its bright outbursts, of which two have been observed in the last two years. If the identity is confirmed, the early observation will be of great use in improving the elements of the comet.

Prof. M. Kamienski (assisted by E. Rybka) continues in *Pub. Warsaw Observatory*, vol. 6, his exhaustive researches on the motion of comet Wolf I. He deals here with the apparition of 1918–19. The observations are numerous and extend from July 11, 1918, to April 1, 1919. The comet was unexpectedly bright, reaching mag. 9½ in November. The observations agree very closely with his previous calculation for the first five months, then the observed R.A. falls behind the calculated one, the amount reaching 19″ in the final group. Prof. Kamienski hopes to remove these discordances by a recalculation of the planetary perturbations from 1884 to 1919.

Stellar Rotation.—Dr. E. A. Kreiken contributes a paper on this subject to the May number of *Mon. Not. Roy. Ast. Soc.* The stars discussed are mainly eclipsing variables and spectroscopic binaries. There are strong reasons for believing that in these close pairs tidal action makes the periods of rotation and revolution equal to each other. Theoretical reasons lead Dr. Kreiken to the formula:

$$\log \text{period} = 1{\cdot}5 \log \text{diameter} - 0{\cdot}5 \log \text{mass} + \text{constant}.$$

This formula differs in one point only from a formula derived empirically by Elvey (*Astro. Jour.*, **71**, 4; 1930). Elvey omitted the term depending on mass. The constant term is evaluated from stars of different classes; the value −0·28 is found from eclipsing variables, −0·04 from spectroscopic binaries with small eccentricity. It gradually rises as the eccentricity increases, and reaches +1·58 for spectroscopic binaries with eccentricity greater than 0 60. This accords well with theory, since period and eccentricity are presumed to increase as the stars grow older.

Dr. Kreiken has not yet used rotation periods derived from the contours of spectral lines: but he hopes to discuss them in the future. He tests his formula on the rotations in the planetary system, but some of his conclusions seem untrustworthy. He assumes that tidal friction in the solar system is inappreciable, and takes the rotation periods of Mercury and Venus as only a few hours. But observations of surface markings make it nearly certain that Mercury rotates in the same time as its revolution, 88 days; while spectroscopic observations make it highly probable that the rotation period of Venus is at least several days. Moreover, following some conclusions of Jeans about the sun's interior, Kreiken takes its rotation period as one sixtieth of 26 days. It does not seem fair to do this for the sun, as the values for the stars presumably are those of their surfaces.

The Significance of the Relationship between Corals and Zooxanthellæ.

By Dr. C. M. YONGE, Marine Biological Laboratory, Plymouth.

BOTH by the publication of his book, "Coral Reefs and Atolls", and by a recent contribution to NATURE,[1] Prof. J. Stanley Gardiner has materially added to the debt which all interested in problems of corals and of coral reefs already owe him. As a result, however, of work on the physiology of corals carried out during the course of the Great Barrier Reef Expedition, I am unable entirely to agree with Prof. Gardiner's conclusions in one important matter. He suggests that corals obtain supplies of carbohydrate from their contained zooxanthellæ, and also that the oxygen produced by the latter as a result of photosynthetic activity is of *vital* importance to the animals. My own conclusions as to the significance of the relationship between corals and zooxanthellæ are somewhat different, and, since this work—the result of the combined labours of Mrs. Yonge, Mr. A. G. Nicholls, and myself—is now largely completed, I am able to put them forward with confidence and no longer tentatively as in previous contributions to NATURE.[2, 3, 4] Moreover, it has proved necessary to publish this work in a series of six large reports,[5, 6, 7, 8, 9, 10] and a short summary of the results obtained is, therefore, not without some justification.

The zooxanthellæ of the Madreporaria are yellowish brown spherical bodies varying in diameter from 6μ to 14μ. Each contains a granular nucleus, one, and occasionally two, pyrenoids around which an amyloid assimilation product accumulates, and vacuolated cytoplasm which contains many oil droplets. The whole is bounded by a stout cellulose wall. They increase rapidly by division into two, but there is no evidence of the formation of spores, nor were they ever found in centrifuged water samples, while all attempts at culturing them outside the body of the animal failed. Unlike the green *Chlamydomonas* present in *Convoluta roscoffensis*, which, as shown by Keeble and Gamble,[11] occur free in the sea and form spores, the zooxanthellæ can live only within the tissues of the coral and are transmitted direct from parent to offspring by way of the planulæ. They are thus definitely degenerate. Within the tissues they occur only in the endoderm, most plentifully in the superficial regions. They are invariably contained within tissue cells, very frequently in wandering cells which convey them from place to place, and their absence from the ectoderm and mesoglœa may be due to the mechanical difficulties of transporting such relatively large objects through the dense material of the mesoglœa.

Although zooxanthellæ never occur in the ectodermal glandular margin of the mesenterial filaments, they may, especially under certain conditions, be very numerous in the 'absorptive' region which lies at the base of this. Degenerating zooxanthellæ are always most abundant in this region, although they may occur anywhere in the endoderm, but always in small numbers in a healthy coral. Boschma[12, 13, 14] has based his views, that zooxanthellæ are digested by corals, on the presence of these degenerating algæ in the 'absorptive' zone, but clear evidence was obtained that this region, as well as being the sole absorptive area, is also the only site of excretion. It is thus the only region of the coral where interchange between the interior of the tissues and the exterior takes place. Degenerating zooxanthellæ present are in process of *excretion* and not digestion.

The pyrenoid of the zooxanthellæ contains chlorophyll which, in the presence of light, forms the amyloid assimilation product (not apparently true starch), utilising carbon dioxide and producing oxygen. Experiments with corals in sealed jars showed that the hydrogen-ion concentration of the water rises appreciably after nine hours in darkness, owing to the accumulation of carbon dioxide, whereas in the light the hydrogen-ion concentration remains constant, because the carbon dioxide is utilised by the zooxanthellæ. In *Dendrophyllia*, a deep-water coral which has extended its vertical range and is not uncommon on the surface of reefs, there is a similar rise in hydrogen-ion concentration in both light and darkness. In common with all deep and cold water corals, *Dendrophyllia* possesses no zooxanthellæ. The carbohydrate formed as a result of photosynthesis is in part converted into oil and stored in that form, as in diatoms and other algæ. Protein synthesis, which involves the utilisation of nitrogen and also of phosphorus and sulphur, was followed by estimations of the phosphorus exchange between corals and the surrounding water. Whereas *Dendrophyllia* excretes large quantities of phosphorus in the same way as any other animal, the reef-building corals which contain zooxanthellæ do not. On the contrary, they frequently remove phosphorus from the surrounding water, even when this has been greatly increased by the addition of phosphate. The zooxanthellæ are thus capable of utilising much more phosphorus than is normally produced by the katabolic processes of the corals in which they live. The same is probably true of nitrogen and possibly of sulphur.

The abundance of zooxanthellæ is thus dependent upon two factors, light and the presence of nutrient substances, carbon dioxide, nitrogen, phosphorus, and sulphur, the latter in turn depending on the metabolic state of the coral. It proved possible to demonstrate experimentally the effect of these limiting factors. In the case of light, comparison between reef-building corals from the surface of the reef and from depths of 7 or 9 fathoms revealed that the former had approximately double the population of zooxanthellæ, while individual colonies from the reef surface which had grown on the under-side of boulders in the absence of light were found practically devoid of zooxanthellæ. The results of an experiment whereby corals were kept in a light-tight box in the sea for 152 days showed that the animals could survive this treatment without obvious harm, but that practically all the zooxanthellæ had died and been extruded at the end of this period. In all cases they were ejected by way of the 'absorptive' zone. Reef-building corals deprived of zooxanthellæ in this way excreted large quantities of phosphate of about the same order of magnitude as *Dendrophyllia*. Sections of such corals revealed that, in place of the zooxanthellæ, there were great numbers of wandering cells with granular contents, and it would therefore appear that these cells normally contain zooxanthellæ, but in the absence of these they resume their original function of excretion. Such wandering cells are a constant and conspicuous feature in the histology of corals, such as *Dendrophyllia* and *Balanophyllia*, which never contain zooxanthellæ.

The metabolic activities of corals were lowered in three ways: by starvation, by heating, and by deprivation of oxygen. In the case of starvation, a series of experiments were set up in which corals were starved (in filtered sea water) and fed (with freshly caught zooplankton) under parallel conditions. In all cases it was found that starved Madreporaria quickly show a great reduction in the bulk of their tissues, and that this is shown equally whether zooxanthellæ are present or not. Almost immediately after starvation begins, zooxanthellæ are expelled in large numbers—some, but by no means all, dead, and practically all intact—and this continues until almost all are extruded. There is no evidence whatever of any digestion of the zooxanthellæ by the corals, or of any transference of material, such as the fat which Keeble and Gamble showed was passed from the *Chlamydomonas* to the *Convoluta*, from the plants to the animal. *Chlamydomonas*, however, possesses *no* cellulose wall. It was conclusively proved that Madreporaria obtain no nourishment whatever from their contained zooxanthellæ, and also that the latter are not even necessary for the initial development and early growth of the newly settled larvæ.

Precisely the same results, so far as the zooxanthellæ are concerned, were obtained when corals were heated to 36° C. for two hours or placed for some days in water almost devoid of oxygen. As in the starved animals, the zooxanthellæ were ejected in great numbers by way of the 'absorptive' zone of the mesenterial filaments, and then passed out through the mouth in mucus strings. The same process was observed in Nature during the summer months when corals on the reef surface were subjected to temperatures of above 35° C. over low-water in the day time, and as a result were almost completely denuded of zooxanthellæ, which gradually multiplied again until, at the end of about three months, the usual content of zooxanthellæ was regained. Here again the extruded zooxanthellæ were intact and apparently alive and healthy when extruded.

In every case, as a result of starvation, heating, or deprivation of oxygen, the metabolic activities of the coral were reduced, and, as a result, the amount of nitrogen, phosphorus, sulphur, and carbon dioxide produced by them was greatly reduced. This lack of the necessary inorganic food materials of the zooxanthellæ is clearly the cause of their expulsion, which is effected by the wandering cells which convey them to the 'absorptive' zone where they are expelled. It is difficult to explain what impels the wandering cells to do this, but it may possibly be the abnormal raising of the hydrogen-ion concentration in the tissues. There is certainly, however, a mechanism here whereby the population of zooxanthellæ is maintained at the level which the metabolic state of the coral, that is the amount of available food, permits. When the population falls below this level, it quickly reaches the maximum possible, owing to the very rapid multiplication of the zooxanthellæ.

Unlike the zooxanthellæ, which are apparently unable to live apart from the animals and are definitely degenerate in so far as they have lost the power to form spores, the reef-building corals can, and, where light is absent, invariably do, live without zooxanthellæ, like all deep and cold water corals. To an individual coral colony the association with zooxanthellæ is *not* essential. Nevertheless, the vast majority of reef-building corals and practically all the Cœlenterata on the reefs possess them, and there can be no doubt that they play an important, probably a vital, rôle in the economy of marine life on a coral reef. This work on the physiology of corals has indicated what the significance of the association may be.

Before proceeding to this, however, the question of oxygen production by the zooxanthellæ must first be discussed. In the presence of light, the zooxanthellæ, as a result of photosynthetic activity, produce oxygen. Exact determinations showed that whereas the oxygen content of enclosed volumes of sea-water in which corals were kept for nine hours in the light might be doubled or even trebled, in the dark it fell to one half, or much less, during a similar period. Corals could be kept in an enclosed volume of water for several week without suffering from lack of oxygen, owing to th presence of this closed system. A series of experiments, carried out over twenty-seven hours continuously, showed that only over the middle of th day, between the hours of 10 A.M. and 3 P.M. approximately, does oxygen production by the zooxanthella exceed oxygen consumption by the coral and th zooxanthellæ. Over twenty-four hours there wa always a drop in oxygen content, showing that th production of oxygen by the zooxanthellæ canno completely supply the wants of the coral. Mr. A. P Orr found that the oxygen tension in pools on the ree surface at low tide at night fell as low as 17·8 per cen saturation, whereas under similar conditions by da it might rise as high as 230·4 per cent. As soon a the sea covered the reef, however, normal condition again prevailed.

In spite of these facts, the benefit derived by th corals from this supply of oxygen is almost certainl more apparent than real. It was found that coral can survive exposure to water of less than 10 per cen oxygen saturation for several days, and that they ca respire equally well in water less than 50 per cen saturated as in water fully saturated with oxygen Under normal conditions, except in sheltered lagoon and other regions where coral growth is slight, the would never be exposed to such conditions; for wate movements around the exposed areas of reefs wher coral growth is invariably most prolific are alway great, and the constant mixing of the water ensure a continuous supply of oxygen. Finally, were th zooxanthellæ absent, the great quantities of nutrien salts excreted by the corals and other Cœlenterat which contain zooxanthellæ would permit of a muc greater growth of phytoplankton, with a consequen increase of oxygen in the water. The zooxanthella are really imprisoned phytoplankton which produc oxgyen within the corals instead of in the sea-wate There is no satisfactory experimental evidence indicating that the oxygen produced by the zooxanthella within the corals is essential to these animals or tha they would not flourish equally well in its absence.

An examination of the feeding mechanisms of mor than forty genera of Madreporaria revealed that coral are carnivores with highly specialised feeding mechanisms for dealing with zooplankton of all sizes. Thi was abundantly confirmed by a study of their digestiv enzymes. Protein alone can be digested extracellularly in the cœlenteron, but only to polypeptides digestion being completed intracellularly where amino acids are formed. Fat also can be digested intracellularly, but very slowly: while the only carbohydrat which can be digested, and that very slowly, is tha found in animal tissues, namely, glycogen. Extract of the mesenterial filaments showed no digestiv action on zooxanthellæ or on any carbohydrate o plant origin. The Madreporaria are thus amongs the most highly specialised carnivores in the anima kingdom, being capable only of digesting anima matter with its constituent proteins, fats, an glycogen.

It is improbable that the small quantities o glycogen and fat which can be digested suffice for th energy requirements of the corals, in spite of thei relatively low needs. It will be necessary, therefore to break down proteins by deaminisation, with consequent accumulation in the tissues of the nitrogen phosphorus, and sulphur split off from the protei molecules in this process. This need for the formation of carbohydrate from protein would explain th remarkably dense population of zooxanthellæ in al healthy reef-builders. If the animal is to functio with maximum efficiency it must rid itself of thes end products of metabolic activity. The excretor system consists of wandering cells, and though these rid the body of excrement quickly enough for the needs of an individual coral colony, it may well be quite otherwise in the case of a large population.

Coral reefs only maintain themselves owing to their remarkable powers of growth in the face of innumerable adverse factors, of which the power of the sea and the action of diverse boring organisms are the most potent. It is essential, therefore, that they should function with the utmost efficiency, and their powers of growth could not but be impaired were excretory products to accumulate in the tissues. But they possess in the zooxanthellæ the means whereby all excrement is automatically removed practically the moment it is formed (unlike photosynthesis, protein synthesis in plants proceeds in darkness as well as in light), and which increases as the tissues grow and the excretion of nitrogen, phosphorus, and sulphur increases. Coral reefs as a whole are largely a closed system, obtaining their food certainly from the zooplankton in the sea, but adding to the dissolved nutrient substances only when they die or expel surplus zooxanthellæ. It appears by no means improbable that the Madreporaria have attained their present great importance in the economy of marine life in tropical waters owing to the aid given to them by their contained zooxanthellæ. In their absence the corals would have been unable to overcome the disadvantages inherent in the simplicity of their structure and of their metabolic processes.

The association between corals and zooxanthellæ is, therefore, essential to the plants, certainly not to individual coral colonies, but probably an indispensable factor in the necessarily exceptional powers of growth and repair possessed by the marine communities known as coral reefs.

New Physics Building at the National Physical Laboratory.

By Dr. G. W. C. KAYE, O.B.E.

BUSHY House at Teddington, which was erected about 1715 by the first Earl of Halifax, a president of the Royal Society and a pupil of Newton, played a not inconsiderable part in the life of the Royal Family of Great Britain. It was, however, destined to fill, after two centuries, an even larger rôle in the life of the nation. In 1900, after many preliminaries, Bushy House was selected as the future home of the National Physical Laboratory, and in 1902 the Laboratory was formally opened by the present King (then Prince of Wales).

Since that date, under the directorship first of Sir Richard Glazebrook and now of Sir Joseph Petavel, a great part of the extensive grounds of Bushy house has been gradually covered by a large collection of buildings devoted to the requirements of the various departments of the Laboratory. During the last few years, these buildings have overflowed on to land acquired for the purpose in the proximity of Bushy Park. But for more than a quarter of a century, physics, the most comprehensive department of the Laboratory, which indeed gives its name to the whole, continued to be inadequately accommodated partly in Bushy House and partly in a number of converted dwelling-houses on the outskirts of the grounds.

Plans for a new physics building were first got out in 1924, and a design prepared by Mr. F. A. Llewellyn, of H.M. Office of Works, was exhibited at the Royal Academy in 1927. The proposed building had a frontage of 295 feet with wings 135 feet in length, forming three sides of a rectangle. The construction of the central portion of the building was begun in January 1929, and the formal opening by Sir F. Gowland Hopkins, president of the Royal Society and chairman of the General Board of the Laboratory, took place on June 23 last.

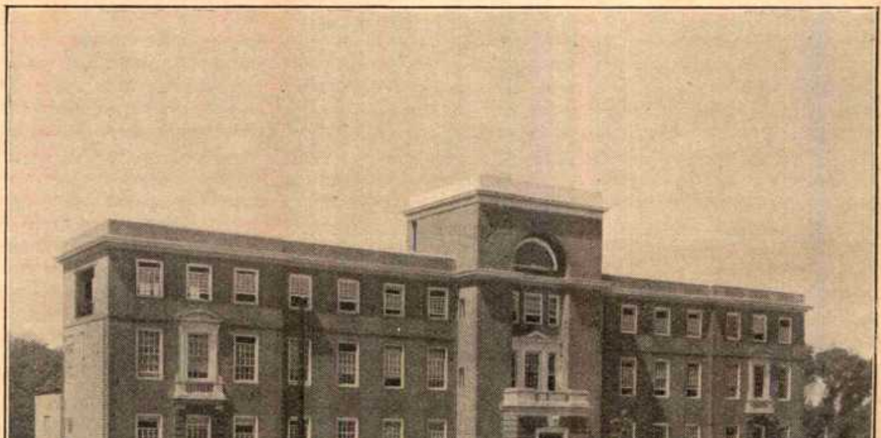

FIG. 1.

The site of the building, which abuts on Bushy Park on two sides, enjoys immunity from traffic noises and vibrations. The structure is mainly of heavy brickwork, which was preferred to a steel-frame building on the score of transmission of noise and tremor. The outer walls are of Crowborough bricks with Daneshill brick and Portland stone dressings.

As will be seen from Fig. 1, the completed portion of the building (of which the frontage is 180 feet) is mainly of three stories, with a central tower. Each storey is wholly on one level. There is a small basement for special purposes. Behind the main block are workshops, industrial laboratories, store-rooms, boilers, etc., all of one storey and semi-isolated from the main building. A large door in the rear of the building is provided with a crane and permits the ready unloading of heavy equipment and stores direct from lorries.

The building is planned on a system of units, all partition walls being non-structural, to facilitate rearrangement of rooms should the necessity arise. In general, the rooms measure about 18 ft. from back to front, the length being either 10 ft., 20 ft., or 30 ft. The heights of the rooms are 16 ft., 14 ft., and 12 ft. on the ground, first, and second floors respectively. In all cases the floors are of concrete, covered with thick cork carpet. Vertical wooden battens are provided at about 3 ft. intervals throughout the walls and ceilings to facilitate the erection of equipment and apparatus. Windows can be quickly darkened by lightproof blinds. Joinery throughout the building is of stained and polished British Columbian pine, except in the entrance hall and landings, where teak has been used.

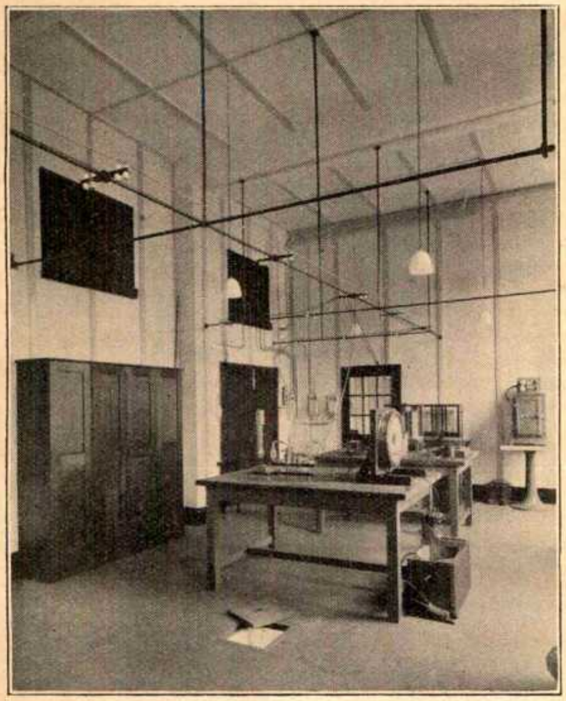

Fig. 2.

The whole of the service mains (electricity, gas, water, etc.) are located in spacious horizontal ducts over the corridors. These ducts, which permit a man to walk along them, communicate with each other by vertical ducts and with the various rooms by doors at 10 ft. intervals. The distribution of the several services to the experimental tables is completed in each room by the aid of an overhead light steel tubular framework provided with insulators for electric cables, and clips for piping, etc. Thus all the services can be brought immediately above a particular apparatus, the lay-out being much facilitated by the use throughout of movable tables rather than of fixed benches. The freedom so gained is enhanced by the provision of sinks let into the floors and provided with loose wooden covers. The usual sinks are, of course, also provided. Many of these details are shown in Fig. 2, which illustrates one of the laboratories.

The electrical services, which are clearly identified by a colour scheme of labels, include 230-volt A.C. at 50 cycles, 240-volt D.C., 110-volt D.C., and 110 volts from a 400-ampere-hour battery. The mains leading from the ducts in the various rooms are connected to 30-ampere switch fuses on the walls, though in the industrial laboratory provision is made for heavier currents.

A system of small service trolleys (of the dinner-waggon type), which can be readily transported about the building, provides sets of accumulators giving low voltage D.C. for steady current work. Experience has shown that this meets the present-day requirements of the Department more satisfactorily than the usual system of split-voltage battery mains. The trolley system is also extended to sets of high-voltage light-current accumulators, and to heavy, costly, or specialised instruments which are only occasionally required by a particular experimenter.

Access to the different floors and the flat roof (which is designed to permit open-air experimental work) is gained by a staircase and passenger lift in the central tower, which also contains an experimental well 70 ft. deep provided with observation platforms.

As at present arranged, the ground floor of the building is devoted largely to investigations on heat: for example, hygrometry, thermal conductivity of metals, refractories, building materials, etc., specific heats of gases, low-temperature research, work for the Engineering Committee of the Food Investigation Board, including a wind tunnel for measuring the exchange of heat between brine-cooled pipes and air passing outside them. There is also a large 200-kilovolt constant-potential generator for operating X-ray tubes used for purposes of 'dosage' and intensity measurements.

The first floor contains the administrative offices, library, etc., and laboratories devoted to investigations in atomic physics, including work on single metal crystals.

The second floor is given over largely to researches on sound: for example, the measurement of noise, the absolute measurement of sound, the calibration of microphones, and the acoustics of buildings. There are large, heavily lagged enclosures to facilitate such work. On this floor also is housed the photographic section of the Laboratory and the departmental drawing office. The end rooms on this floor can have one side opened wide to the outer air should the necessity arise.

The basement affords accommodation for constant-temperature rooms, a reverberation chamber for measurements of acoustical coefficients of absorption, and equipment for photographing sound pulses and water ripples. There are store-rooms in the basement for housing records and special equipment and material, such as radium. The Laboratory, it will be recalled, is responsible for the custody, distribution, and testing of radium for the National Radium Trust and Radium Commission. Facilities are also provided in the basement for projecting cinematograph films.

The part of the building already constructed will house the Heat and General Physics Section of the Physics Department, with part of the radiology and sound work. It is hoped during the next few years that sanction will be obtained for the erection of the wings, so that the remainder of the Radiology Section and the temperature standardisation work can be transferred from the dwelling-houses and other buildings in which they are at present accommodated. The quadrangle will be completed by the Acoustics Building, the erection of a section of which has recently been approved.

The Pulp-Wood Market in the United States.

UNDER the arresting headline "Russia seizes Canada's Market", the *Monetary Times* of Toronto (Jan. 2, 1931) discusses the position of the pulp-wood market, a position which is not without interest for Europe. In 1924, under the heading "The Mistaken Idea that Canada has a Monopoly in Wood", the Canadian Pulpwood Association in a memorandum to the Royal Commission on Pulpwood wrote: "Contrary to the prevailing idea, it must not be overlooked that if the American is forced to turn away from Canada for raw materials, he will find that we have not by any means a monopoly. For instance, wood from Russia, in large quantities, is already freely quoted, by substantial concerns, for delivery at Atlantic seaports. If the U.S. operator has the Canadian door shut in his face, he will naturally consider it to his interest to encourage forestry conservation and development intensively in the United States to ensure independence as far as possible."

The memorandum went on to point out that research would be stimulated, that so far as possible existing American hardwoods would be utilised, and that already there had been a remarkable development in the use of the long-leaf southern pine in the kraft industry. In short, that there was a possibility that, in the attempt to take advantage of America's extremity by the threat of pulp-wood export restrictions, Canada might find that she had jeopardised a valuable trade connexion in paper products, encouraged her chief customer to develop her own resources, whilst unconsciously encouraging her trade with other countries.

To-day these predictions are coming true. America has been busily engaged in investigating every source of pulp-wood supply, an absolute necessity to her, owing to her enormous consumption of pulp. One of the new sources of supply has proved to be Russia. This year, Russian shipments of the highest quality of wood, amounting to some 300 cords, are being delivered in the eastern States at the same price as Canadian wood. Further, Canada gave transportation preference to the Russian wood; for the latter, landed at the Canadian ports of Sorel or Three Rivers, was for a time carried to the United States by Canadian railways at lower freight rates than these railways gave to Canadian wood for precisely the same movement.

The other possibility predicted, that America would undertake research with the object of endeavouring to make use of materials of her own not previously utilised for the pulp trade, has also been verified by the already mentioned development of the long-leafed southern pine in the kraft industry; and there is another interesting outcome. Dr. C. H. Herty, former president of the American Chemical Society, recently announced to the Atlanta Chamber of Commerce that he had succeeded in producing high grade newsprint paper from southern slash pine, cooked in the same digester and under the same conditions as spruce. The importance of this research work becomes evident when it is understood that there are vast reserves of this timber in the southern States, and that this variety of southern pine had always been regarded as the least capable of producing regular newsprint.

The above description of the present position in the pulp industry in the New World carries some important lessons for Europe. It displays the close and accurate study made of world-wide forest resources and the thorough knowledge of the pulp-wood industry which exists on the other side of the Atlantic. It also throws a strong light on the attitude taken up and ideas expressed since the War in some quarters in Britain upon the small influence the Russian coniferous forests were capable of exerting on the markets.

University and Educational Intelligence.

LONDON.—The degree of D.Sc. has been conferred on the following: W. Youngman, for a thesis entitled "Further Studies in the Cytology of the Hibisceæ", with two subsidiary contributions; S. E. Hollingworth, for a thesis entitled "The Glaciation and Physiographic Development of the Eden Catchment Basin West of that River, and the Drumlins of Edenside and the Solway Basin", with two subsidiary contributions; Lin. L. Lee (Rothamsted Experimental Station), for a thesis entitled "The Influence of Geology and Climates on Soil Types" (*Jour. S.-E. Agric. Coll.*, June 1931); A. N. Puri (Rothamsted Experimental Station), for a thesis entitled "Studies in Soil Colloids" (*Memoirs of Dept. of Agriculture*, 1930; *Soil Science*, 1930–31); A. J. Maslen (Chelsea Polytechnic), for a thesis entitled "The Structure of *Mesoxylon Platypodium* and *Mesoxyliodes*" (*Annals of Botany*, July 1930); L. R. Underwood (Imperial College—City and Guilds College and East London College), for a thesis entitled "The Combustion of an Oil Jet in an Engine Cylinder".

THE following fellowships for the year 1931–32 have been awarded by the Salters' Institute of Industrial Chemistry and approved by the Court of the Salters' Company: J. L. Sweeten (St. Catherine's College, Cambridge) and Norman Stuart (Imperial College, London). Fellowships have been renewed to: D. L. Hodge (Imperial College, London), D. J. Branscombe (University College, Exeter), J. Hofton (Caius College, Cambridge), and H. G. Simpson (East London College). The Salters' Institute has also awarded one hundred and thirteen grants-in-aid to young men and women employed in chemical works, to facilitate their further studies.

THE Ramsay Memorial Fellowship Trustees have made the following awards of new fellowships for the year 1931–32: Dr. B. K. Blount, a fellowship of £300, tenable for two years, at the University of Oxford; Mr. Ragnar Ericson, a Swedish fellowship of £300, tenable for two years, at the Imperial College, London; Dr. George Karagunis, a Greek fellowship of £400, tenable for one year, at University College, London; Dr. J. Lens, a Netherland fellowship of £300, tenable for two years, at University College, London; Dr. Y. Urushibara, a Japanese fellowship of £400, tenable for two years, at University College, London. The Trustees have renewed the following fellowships for the year 1931–32: Mr. W. R. Angus (British fellow), University College, London, and Dr. James Bell (Glasgow fellow), University College, London.

Birthdays and Research Centres.

Aug. 23, 1869.—Dr. R. T. Gunther, curator of the Lewis Evans Collection of Historic Scientific Instruments in the University of Oxford.

I am especially interested in the discovery of ancient scientific instruments and specimens, and in their preservation for illustrating the history of the natural sciences. It has been only too frequently a common experience in the laboratories of our universities that with every change in the directorate a quantity of unique apparatus of great scientific interest has been scrapped. It is with the view of checking the wastage of apparatus of special historic or artistic value that the Lewis Evans Collection has been founded. Incidentally, the benefaction of Dr. Evans has led to the restoration (in part) of the Old Ashmolean, the oldest museum of natural history in Britain, and quite recently to the discovery of some of Edward Lhwyd's type specimens of British fossils, long believed to have been irretrievably lost.

Aug. 23, 1886.—Prof. W. Stiles, F.R.S., Mason professor of botany in the University of Birmingham.

In the near future I hope to see considerable development of our knowledge of the physiology of plants and the application of this knowledge to various plant industries, including agriculture, horticulture, and food storage.

My own researches have dealt mainly with problems of cell physiology, particularly with those of absorption of substances by living cells, and the passage and movement of substances from cell to cell in the organism. While continuing work on this subject, I am also engaged on an investigation of the relation between the chemical and physical constitution of substances and their toxic action on plant cells and tissues. Latterly I have turned my attention to the very fundamental questions of respiration and photosynthesis by plants, and am investigating these processes by methods specially developed for the purpose.

Aug. 24, 1880.—Dr. A. D. Imms, F.R.S., chief entomologist at the Rothamsted Experimental Station, Harpenden, Herts.

My duties involve keeping abreast with many aspects of entomology. At the same time, the writing of a comprehensive text-book on the subject has absorbed much time and energy during the past few years. The modern trend of the subject, as with other branches of zoology, is towards its biological and physiological aspects. An entomologist well trained in physiological technique has a wide field in front of him. On the biological side, more exact methods of study of insects in relation to their environments are likely to yield results of both fundamental and economic significance. At the same time, there is a shortage of scientific taxonomists of broad outlook, specialists in the parasitic groups of Hymenoptera, for example, being especially few and far between. My own investigations deal chiefly with parasitism, its effects upon the hosts concerned, and the differential influence of environmental factors on host and parasite.

Aug. 25, 1844.—Sir Thomas Muir, C.M.G., F.R.S., formerly Superintendent-General of Education in Cape Colony.

Firmly believing that in the advancement of science every little addition counts, I continue to work at quite minor problems, leaving them to be suggested by my own casual reading or to be brought to my notice by fellow-students from near or far. Fairly often I am able to pay such a correspondent back in his own coin with interest, and so I derive now and again the pleasant satisfaction of seeing a more vigorous brain dealing effectively with a worthier type of work.

I thus welcome the present occasion as giving me the chance of influencing by suggestion a much wider circle of workers: and I select as a subject urgently requiring attention the determinantal properties of oblong arrays. Naturally the first business would be to search out and tabulate the already known results from those of Bézout in 1779, all the while noting contrasts, analogues, and possible generalisations. Even such preliminary labour would in every case reward the worker: and thoughtful afterstudy would almost certainly give something of value to us all.

Aug. 26, 1863.—Mr. Edward Heawood, Librarian to the Royal Geographical Society.

My special studies for many years have been the history of exploration and early maps. At the moment I am chiefly interested in the beginnings of topographical survey and mapping in England and the early history of paper-making and the paper trade. Both these subjects, especially the latter, have so far been more or less neglected. Many early maps, for example the English version of the world-map of 1544 generally known as Sebastian Cabot's, or John Norden's map of Kent of about 1595 (among many others), remain to be discovered, and a systematic search in old libraries might bring some at least to light. Practically no information is available on early paper-making in Great Britain, but the subject is of importance in connexion with the dating of old documents or other bibliographical problems.

Aug. 26, 1873.—Prof. W. A. Osborne, professor of physiology and dean of the faculty of medicine in the University of Melbourne.

Two problems of gel behaviour interest me at present. (1) Fresh defibrinated blood diluted with a twofold volume of water is laked and is transparent. Addition now of sodium chloride to restore the original osmotic pressure brings back opacity and reflection of light. (2) The cornea in contact with solutions not iso-osmotic with blood behaves as a gel, allowing rapid diffusion of chlorides but slow diffusion of sulphates either way. When the cornea is in contact with iso-osmotic solutions, diffusion of chlorides is uni-directional and towards the aqueous (confirmatory of F. P. Fischer). The question is whether this valved diffusion is due to living epithelium.

Aug. 27, 1865.—Prof. James H. Breasted, director of the Oriental Institute, University of Chicago.

I am endeavouring to trace the course of human development from the merely physical man disclosed by the palæontologist to the rise and early advance of civilised societies, the product of social evolution culminating in social idealism.

The scene of this evolution has unquestionably been shown to be the ancient Near East—the region folded like a horseshoe around the eastern end of the Mediterranean. The diverse civilisations which arose there are now known to have been the background and basis of European civilised development. These countries to-day constitute an almost inexhaustible storehouse filled with perishing and still unsalvaged evidence disclosing early human development. There has been no comprehensive and systematic effort to save and study this enormous body of perishing evidence *as a whole*. These facts lay a twofold responsibility on modern science: first, the task of salvaging this evidence by scientifically organised and equipped field expeditions; second, the study and constructive interpretation of this evidence.

These responsibilities adequately met will require not only scientific training and method on the part of the *individual*, but also organised effort and funds surpassing those which have been available in humanistic research hitherto. The organisation which I have hoped might contribute to meet this situation, the Oriental Institute of the University of Chicago, is now twelve years old. It maintains a series of twelve field expeditions operating along a front of more than 2000 miles, from the southern shores of the Black Sea on the north, eastward to south Persia (Persepolis), and thence to north-east Africa and the Upper Nile on the south. Its administrative and scientific headquarters, a new building at the University of Chicago, houses a series of research projects and serves as a focus on which converges the new evidence from the excavations and the salvaging operations of the field expeditions.

The subject matter of these researches both at home and abroad—the rise of man—is a process which in itself constitutes the greatest event in the history of the universe so far as it is known to us. The purpose of these researches is eventually to make possible an understanding of human origins and early human advance, based on fuller evidence than has ever been available before, and in so doing perhaps to discern more fully something of the causes and the nature of that mysterious and persistent buoyancy of the human spirit which, in spite of declining intervals, has made the direction of human movement from the beginning —and for probably several hundred thousand years— a rising line.

Aug. 28, 1858.—Prof. ROLAND THAXTER, emeritus professor of cryptogamic botany and honorary curator of the Farlow Herbarium, in Harvard University.

I am publishing this summer my fifth quarto memoir on the taxonomy of the Laboulbeniales (*Memoirs American Academy of Arts and Sciences*, vol. 16, part 1, pp. 1-435, with 60 plates), illustrating many new and curious generic and specific types, and am planning to begin the preparation of a sixth and final part, to include the genus *Laboulbenia* and various addenda, with a general summary, host-index, etc.

Societies and Academies.

PARIS.

Academy of Sciences, June 22.—The president announced the death of Jacob Eriksson, *Correspondant* for the Section of Rural Economy.—**H. Deslandres**: Simple relations between the molecular spectrum and the structure of the molecule. A table of the infrared frequencies of gaseous ammonia and carbon dioxide, and a discussion of the data.—**Charles Achard and Augustin Boutaric**: Some physical properties of the blood serum in lipoid nephrosis. Quantitative measurements of the light absorption and viscosity, before and after heating the blood serum to varying temperatures, are used for determining the changes in the number of particles in the colloidal suspension. The theoretical basis of the method was described in an earlier communication (*C.R.*, **191**, 1332).—**R. Fosse, A. Brunel, and P. E. Thomas**: The quantitative analysis of very small quantities of allantoin at high dilutions. The application to human urine. The method is based on the destruction of urea by the diastases of the soja bean in presence of cyanide, followed by hydrolysis by hydrochloric acid. The glyoxylic acid thus produced from the allantoin is estimated by a colorimetric method with phenylhydrazine; full working details are given.—**C. Sauvageau**: Three new examples of plethysmothallus (*plethysmothalle*) (*Myriotrichia* and *Protasperococcus*).—**Paul Delens**: Orthoptic congruences and isotropic congruences.—**W. Sierpinski**: A property of the limits of ensembles.—**M. Kourensky**: The variation of the arbitrary constants for the integrals of ordinary differential equations of the second order.—**Florent Bureau**: Holomorph functions in a circle of finite radius and integral functions.—**Gabeault**: The air resistance to ballistic velocities.—**M. Aubert and R. Duchêne**: The determination by the photographic method of the resistance of petrols to detonation.—**D. Barbier**: Function of distribution of the eccentricities and mean anomaly of long period visual double stars, the orbits of which have not yet been calculated.—**G. Foex and Mlle. B. Kessler**: The various magnetic states of the nickel ion in solutions of its chloride. Moderate rise of temperature (to 90° C.) does not influence the magnetic state of the nickel ion, but raised to a higher temperature (100° C.) the Weiss magnetons are lowered.—**Horia Hulubei and Mlle. Yvette Cauchois**: The monochromatic stimulation of Raman spectra in the ultra-violet. Applications. The monochromatic radiation was obtained by filtering the light from a mercury lamp through chlorine gas under pressure. Details of experimental results with water and ethyl alcohol are given.—**P. Dupont**: Study of the hydrolysis of sulphate of zinc solutions with the aid of the quinhydrone electrode.—**M. Haïssinsky**: A new reaction of polonium. Polonium forms an insoluble pyrogallate: in this reaction it resembles bismuth and antimony, but differs from tellurium.—**Mlle. Germaine Bernheim**: The preparation of the cyanamides of the earths and alkaline earths. Study of the reaction

$$C_2N_2 + MO = CN.NM + CO$$

as a function of the temperature, where M is barium, strontium, magnesium, zinc, cadmium, or beryllium.—**Pierre Jolibois and Georges Chaudron**: A new method for getting calcium triphosphate in a soluble form. The method is based on the conversion of the mineral phosphate into an insoluble lead chlorophosphate, followed by treatment with nitric acid. The process is worked in a cycle, with recovery of lead, and the products are ammonium nitrate and ammonium phosphate containing a little ammonium nitrate, both of which can be used as manures.—**Al. Yakimach**: Phosphate of trivalent manganese and of aluminium. An account of the preparation and analysis of $(NH_4)H_2Mn(PO_4)_2$, $(NH_4)H_2Al(PO_4)_2$, $KH_2Al(PO_4)_2$, and $Ca[H_2Al(PO_4)_2]_2$.—**Malaprade and Schnoutka**: The separation and estimation of boric acid and alumina. The alumina is separated as a basic sulphite, the excess of carbon dioxide and sulphur dioxide removed by boiling, and the boric acid in the filtrate estimated by the usual double titration.—**André Kling and René Schmutz**: The decomposition of solutions of sodium hypochlorite (Javel's liquid).—**Georges Darzens**: A method of separating the cresols and the properties of pure *m*-cresol. The method is based on the formation of a stable addition compound of *m*-cresol and dry sodium acetate: the *p*-cresol forms an addition compound with oxalic acid.—**Picon**: Silver camphocarbonate. Chemical organosols of silver.—**E. Urion**: 1, 2-cyclohexanedione or dihydropyrocatechol. This α-diketone has been isolated from the products of decomposition of divinylglycol by reduced copper at 280° C.—**Robert Lantz and Georges Mingasson**: Researches on the napthalene bisulphite compounds. The abnormal action of sodium bisulphite on certain derivatives of β-oxynaphthoic acid.—**Ch. Courtot and Chaix**: Study in the diphenylene sulphide series.—**N. Kouriatchy**: The layers of serpentines and chromites of Togo.—**Paul Cristol**: The hæmorachidian equilibrium of the bicarbonates.—

Mlle. Choucroun: The hypothesis of mitogenetic radiation acting on the multiplication of bacteria. An account of experiments tending to negative the hypothesis of a mitogenetic radiation or of any action through the walls of the tube containing the bacteria; if the latter vessel is corked, the action ceases.—**Edouard Ducloux** and **Mlle. Georgette Cordier**: The study of certain humoral modifications arising in the course of experimental bovine marginal anaplasmosis.—**Denis Bach**: The mechanism of the antiseptic action of lactic acid on *Bacterium coli*.—**Georges Blanc** and **J. Caminopetros**: The virus of exanthematic fever is hereditary in the tick *Rhipicephalus sanguineus*.

Cape Town.

Royal Society of South Africa, June 17.—**Gunnar Nygaard**: Freshwater Algæ and phytoplankton from the Transvaal. The phytoplankton was found to be in general a typical pond-plankton, with *Microcystis aeruginosa* and *Botyococcus Braunii* sometimes becoming dominant. That of the larger river-dams was often dominated by the diatom *Melosira*, which West found to be the chief form in Lake Nyassa. Both lakes and pans appear to be rather poor in species of Algae, only 98 species and varieties being found in the samples, of which six species and five varieties are new. Two noteworthy finds were *Draparnaldia Ravenelii*, a species not found since 1887, when it was described from North America, and a new Coscinodiscus, *C. incomptus*, a freshwater species of this otherwise typically marine genus.—**F. Rich**: Phytoplankton from South African pans and vleis. 262 species and varieties were found, among which were nine species and eight new varieties, as well as several new forms. The occurrence of *Pleodorina californica* is interesting, for this genus had not been recorded for South Africa. The marked differences found in the plankton from various bodies of water is noteworthy, suggesting that an interesting correlation of this with the chemical and physical characters of the water could be made by collectors in South Africa.

Sydney.

Royal Society of New South Wales, June 3.—**Daphne L. Coulston**: (1) A new colorimetric method for measuring the hydrogen ion concentration of natural waters. This method consists of comparing the intensity of colour produced when the indicator, para nitro phenol, is added to the solution of unknown hydrogen ion concentration with a standard depth of colour in a Dubosq colorimeter. The results have been checked by comparing buffer solutions of known hydrogen ion concentration with the standard.—(2) The splenectomy of tadpoles. The object of the investigation has been to ascertain whether the absence of the spleen influenced the metamorphosis of the larval frog. Frogs used in the experiments belonged to various species of *Limnodynastes*. The tadpoles were about 7·5 cm. in length, and possessed small hind limbs. Urethene was used as an anæsthetic. Six splenectomised and ten normal tadpoles developed similarly over a period of three to four weeks. No deep regeneration had taken place during one month.—(3) Variations of the hydrogen ion concentration of sea water. Of numerous samples taken off the coast at Cronulla, La Perouse, Bondi, Manly, Collaroy, etc., 60 per cent showed a pH of 8·5 and 40 per cent of 8·4. These results were obtained using phenol red as an indicator. As samples were taken in Port Jackson the alkalinity of the water decreased perceptibly within a mile from the Heads. Increase in the tension of carbon dioxide decreased the alkalinity. Sea water is only slightly buffered, since so small an increase as 8 millimetres tension carbon dioxide sufficed to alter pH from 8·5 to 7·0.—(4) On the metabolism of cold-blooded animals. Experiments have been made to determine the carbon dioxide expired and the oxygen absorbed for resting frogs and to relate the figures obtained to the surface area of the frogs. Surface area was determined from plasticene moulds lined with silk. The silk was then separated from the cast, cut into fragments so as to lie flat, and reproduced on sensitised photographic paper. The affected areas were cut out and weighed and from the weight of paper the surface area calculated. A frog weighing 30 gm. has a surface of approximately 100 sq. cm. The metabolism of the frog was obtained by placing it in a wide-mouthed jar of rather more than 1 litre capacity, the jar being closed with a rubber stopper through which inlet and outlet tubing passed. Metabolism diminished during starvation and increased two to three times by a rise in temperature of 10° C. Resting frogs produced about 20 calories per sq. cm. of body surface per day.—**H. F. W. Whitworth**: The mineralogy and origin of the natural beach sand concentrate of New South Wales. Attention is directed to the fact that whilst, in the past, the heavy mineral concentrates have been worked intermittently for their gold, platinum, and tin values, their future value probably lies in their zirconium and titanium contents. The composition of the sand concentrates is given in detail, both chemical and mineralogical analyses being quoted, with descriptions and sketches of individual minerals. The heavy minerals of which the concentrates are formed have been derived, in all probability, from the Triassic sandstones which overlie the Coal Basin between Newcastle and Bulli.—**J. C. Earl** and **Miss T. M. Reynolds**: The celluloses of two water plants. The cellulose of *Eichornia crassipes* and *Ottelia ovalifolia* were isolated and compared by means of their triacetates with the normal cotton type of cellulose. Although the separation from associated substances was difficult to carry out, the cellulose from each of these plants appeared to be of the normal type.

Diary of Societies.

Saturday, August 22.

North of England Institute of Mining and Mechanical Engineers (Annual General Meeting) (at Newcastle-upon-Tyne), at 2.30.—Open for further discussion:—Interim Report of the Support of Workings in Mines Committee, A. Walker.

Tuesday, August 25.

London Natural History Society (at London School of Hygiene and Tropical Medicine), at 6.30.—Informal Meeting—Ornithology.

Quekett Microscopical Club (at 11 Chandos Street, W.1), at 7.

CONFERENCES.

August 25 to 29.

Conference of the International Institute of Bibliography (at the Hague).

Aug. 25.—Prof. A. Pollard: Presidential Address.

Aug. 26.—E. Morel: Statistique du livre en France et son aspect bibliographique.
  Dr. J. Vorstius: Index Bibliographicus.
  Sir Frederic Nathan: International Abstracting and Indexing of Scientific and Technical Literature.
  J. M. C. Muller: Rapport sur le Repertorium Technicum.
  J. Gérard: Création d'une Fedération Française des Offices de Documentation.

Aug. 27.—Dr. R. Sand: La documentation dans le domaine de la médicine.
  Dr. E. Huet: L'Organisation de la Documentation Dentaire par la Féd. Dent. Int.
  Dr. J. G. Priestley: Bibliography of Physiology and the Application thereto of the Decimal Classification.
  Dr. M. Pflucke: Aufgaben und Organisation eines Referatenorgans.
  B. du Retail: Le Centre d'Information Economique de Paris et son Service de Dossiers de Presse.
  B. M. Headicar: The Bibliography of Economic and Social Sciences.
  E. de Grolier: Le classement standardisé appliqué dans la librairie

Aug. 28.—Various Papers.

Aug. 29. Excursions

August 31 to September 4.

International Congress of Neurology (at Berne).

SATURDAY, AUGUST 29, 1931.

Creative Science and Industry.

WHILE it would be difficult to find a more brilliant example of the value of creative science to industry than the experimental investigations of Michael Faraday, there is a tendency to regard such contributions of science as exceptional. Even on this point it is pertinent to recall the verdict of Huxley in 1877 in urging the value of technical education: "If the nation could purchase a potential Watt, or Davy, or Faraday at the cost of a hundred thousand pounds down, he would be dirt-cheap at the money. . . . What these men did has produced untold millions of wealth in the narrowest economical sense of the word." In scientific research, quality counts supremely, but industry owes an incalculable debt to innumerable investigators engaged in scientific research directed by no other motive than the pursuit of knowledge.

At the moment, our interest is centred chiefly on the discovery of electromagnetic induction by Faraday and its consequences—electrical industry and its ramifications of the present day. The dyestuffs industry is, of course, the classical example of the relation of scientific research to industry, and it is worth recalling that this industry owes much to Faraday's discovery of benzene. Chemical industry abounds in similar examples. The manufacture of synthetic drugs may be traced back to such purely scientific work as Kolbe's synthesis of salicylic acid, and its expansion has invariably been connected with external scientific work like Knorr's discovery of antipyrine, Ehrlich's salvarsan, Fourneau's 309, Kraut's aspirin, Molle and Kleist's veronal, the isolation and synthesis of adrenaline, Banting and Best's isolation of insulin, Kendall's preparation of thryoxin and its brilliant synthesis by Harington. Pasteur's scientific investigations on yeast prompted by a brewing difficulty led him to the discovery of the whole theory of fermentation, the existence and action of bacteria, thence to the pasteurisation process, and finally to the discovery of the antitoxin of hydrophobia. These discoveries have not merely transformed the brewing, yeast, dairy, and cheese industries, but have also led to the rise of important new branches in the production of solvents such as acetone and butyl alcohol by fermentation. It would be difficult to measure the debt of either the fermentation industries or, indeed, of humanity to the scientific work of Pasteur, whose chance discoveries were so momentous because he was prepared.

When we turn, however, to such men as Ludwig Mond and Sir William Siemens, whose names are pre-eminently associated with industry, we find once more that the technical processes associated with them equally had their origins in scientific research. Long and patient investigations led to the discovery of nickel carbonyl, and the Siemens process was similarly the outcome of the scientific study of heat economy. The remarkable progress during the last two decades in the metallurgical industries is also based on purely scientific investigations—metals such as tungsten, molybdenum, vanadium being little more than curiosities for years after they were discovered.

Even in our older industries, scientific research has been responsible for revolutionary changes and developments. The art of soap-making has been transformed into a science. Sabatier's observation of the hydrogenating properties of finely divided nickel is the germ from which has developed the industrial hydrogenation or hardening of oils and fats and innumerable processes in almost every section of organic chemistry, including the Berginisation process for obtaining liquid fuels from coal. Scientific investigations on nitrocellulose and cellulose acetate and their solvents have led to the discovery of lacquers which have not only revolutionised the paint and varnish industry but have also made possible the enormous expansion of the automobile industry. The leather-substitute used extensively in upholstering motor cars has itself been produced by industry as an outcome of the scientific investigation of nitrated cellulose. Equally important is the development of the whole rayon industry from scientific investigations and observations in the same field of cellulose—Chardonnet's discovery of nitrocellulose silk and Cross and Bevan's viscose. The technical possibilities of any one of these discoveries were scarcely dreamed of by industry when the first investigation was commenced. Finally, the great fertiliser industry, including the fixation of atmospheric nitrogen, is essentially based on Liebig's discovery of the superphosphate process and Lawes and Gilbert's patient investigations on the effect of fertilisers on plant growth, and from Sir William Abney's measurements of the absorption of light by silver halide emulsions have came the advances of modern photography leading ultimately to the cinematograph industry.

We might continue the story by referring to other industries, and particularly to the electrical industries, which have been developed from Faraday's discoveries in electricity and magnetism and from Maxwell's and Hertz's investigations on electromagnetic waves, but limitations of space forbid. We have only discussed one aspect, however, of the contribution of science to industry. Equally important is the contribution which science makes in technique—the provision of new technical methods. The importance of this aspect of the service of science to industry was enforced on British industry in the early days of the War, when our dependence on continental firms for all classes of scientific instruments and glassware imposed a considerable handicap on the expansion of the munitions and other industries to meet the war-time demand. Without the instruments of precision for measurement and control of temperature, pressure, refractivity, and other properties, which have been evolved by purely scientific work, industrial development would have been much more laborious. Essentially modern advances in the measurement of high temperatures paved the way for the developments in the metallurgical industries. The development of the newer industries such as the radio industry, the manufacture of synthetic resins and rayon, is indeed a record of advance closely related to the utilisation not merely of scientific discoveries but also of scientific methods and scientific instruments for purposes of control.

The significance of such methods of X-ray analysis, ultra-violet light, hydrogen ion determination, thermionic valves for control purposes, including automatic control, in industry is only now being appreciated. In high-pressure reactions as well as low-pressure reactions and distillation in very high vacuum, science has provided industry with a whole range of new technique. Scientific work on the two forms of hydrogen has recently simplified the evaluation of industrial catalysts, while almost simultaneously the discovery of the selective properties of a copper chromite catalyst has enormously increased the possibilities of development in the industrial hydrogenation processes.

X-ray methods themselves provide a striking example of the reaction on industry of scientific technique. The recent application of X-ray methods to textile research has led to discoveries relating to the structure of cellulose, wool, and hair which throw new light on just those typical properties of wool which are of fundamental importance in manufacturing operations. As a result, a correct interpretation of the conditioning, dyeing, and other absorptive processes has been facilitated and a method elaborated for measuring the surface scale structure of the wool fibre which represents the first step towards placing the important technical operations of milling on a scientific foundation. In addition, the discoveries *suggest* an interpretation of the structure of cellulose which has a direct bearing on the mercerisation process.

While science has thus provided industry with instruments of precision and methods of attack on technical problems, an important contribution has also been made in the field of industrial health and safety. Until science had revealed the cause of yellow fever and the methods of its prevention and control, the resources of the engineer were inadequate to construct the Panama canal. Merely to walk through a modern dry battery or accumulator factory is to realise how medical science, by examining the causes of industrial poisoning, dusts, and their prevention, has revolutionised conditions of work. Hundreds of industrial processes operate smoothly every day because the scientific study of the properties of materials has enabled working conditions to be devised which satisfy stringent requirements of safety and efficiency.

In the past hundred years, industry has come to adopt not only the results of scientific discoveries but also scientific methods both for the development of new processes and for the control and improvement of existing processes or products. Individually or collectively, progressive industrial firms are now invariably associated with research departments or institutions in which the investigation of technical problems is systematically undertaken. Such technical research work will, however, usually be restricted either in the subject or the object of the work, and occasionally in both, leaving the investigator only freedom to select his methods. Without detracting from the merits of such work, which frequently compares in brilliancy with the ablest research conducted at the universities, the importance of fundamental scientific investigation, with its full freedom of aim, method, and materials, must not be overlooked. Great as has been the service of science to industry in improving or elaborating technique, it is from the fundamental discoveries of creative science that industry has derived its greatest benefits. While recent *rapprochements* between the universities and chemical industry indicate that this is fully realised, at any rate by chemical industry, economic reasons limit the possibilities of fundamental research being organised in industry. Authorities like Sir Harry McGowan and Dr. Levinstein have recently stressed the relations between industrial research and profits which influence the research policy of any sound industrial organisation, and Major F. A. Freeth has pointed out that the drift of modern life is against discovery. The vertical organisation of industry and of science restricts the exchange of technique, upon which probably the technique of discovery largely depends.

We are, however, as far to-day from a technique of discovery as when Francis Bacon wrote his " Novum Organum ". A century of industrial progress testifies to the interdependence of science and industry. The great names on science's roll of honour are again and again to be found on the roll of the greatest benefactors of industry and of humanity. There is no truer touchstone of the sincerity of the tributes paid by industry and the State to the memory of Michael Faraday than the volume of support accorded to scientific research in Great Britain and elsewhere, and although we live in times of unprecedented depression, we must maintain the facilities, the institutions, and the technical and monetary equipment which will make it possible for others, though like Faraday of humble birth, to devote their splendid gifts unhindered to the service of mankind. The dynamo, broadcasting, the aeroplane, the cinematograph were not further beyond the imagination of Faraday's listeners in the Royal Institution than future developments from our own, if creative science continues to exert its fertilising influence on industry and the ties between discovery and service are knitted closer through the whole fabric of modern life.

Nansen's Last Journey.

Through the Caucasus to the Volga. By Fridtjof Nansen. Translated by G. C. Wheeler. Pp. 255+23 plates. (London: George Allen and Unwin, Ltd., 1931.) 12*s*. 6*d*. net.

IN 1925 Nansen visited Armenia on behalf of the League of Nations as one of a commission of five appointed to investigate the possibility of settling refugees from Turkish Armenia on the land. An earlier book, " Armenia and the Near East ", was a record of the mission up to the end of its labours in Erivan. Nansen now reopens the story in the train as he leaves Armenia on July 2, 1925; but he does not get into the swing of his narrative until he reaches Tiflis. Here he opened negotiations with the Transcaucasian Federation of the three republics, Armenia, Georgia, and Azerbaidjan, with the view of raising a loan in order to carry out the proposals of the Commission—a project which, he tells us, later failed to mature.

Nansen made a short stay in Tiflis, of which he gives a brief description. He speaks of the manifold different races to be seen in its streets and of the varied and cosmopolitan origin of its merchandise. He notes the fact that coats of mail, swords, iron-bound shields, and helmets, " such as might well be relics from crusading days ", are still offered for sale and, what is more, are worn by the mountain tribes of the remote Caucasian valleys. What he found most striking, however, was the " great seriousness which wraps all these people and the little show there is of any kind of joy in life ". The War brought many changes. What was left undone towards the ruin of the country was completed by the suicidal economic policy of the early days of the independent republic ; and on top of that came the Bolshevik invasion. In two respects, however, Georgia appears to have suffered little change. Nansen records that someone who was to meet him on Wednesday at one o'clock turned up at twelve on the following day, apologising for coming a little late. Nor have the Georgians lost their gift for, and appreciation of, opera, drama, and the ballet. It is here stated that when the Soviet government wished to suppress the ballet on the ground of expense, the whole working-class population petitioned against this action. As a matter of fact, before the War the opera in Tiflis was the centre of social life and the opera house the second largest in the whole Russian Empire.

It is a pity that Nansen's stay in Tiflis was not prolonged. It would have been instructive to have had the reflections of his more extended observation of a people of such an individual and distinctive character in their present changed and economically strenuous conditions.

Nansen left Tiflis by car, motoring through the Caucasus range to Daghestan, where he was to stay with Samursky, the president of the Daghestan Republic, whom he had met in Moscow. The Vladihavkas road, by which he travelled through the only pass over the range, is the great military road laid down by the Russians for their final conquest of the Georgians at the beginning of the nineteenth century, and along which the Bolsheviks advanced when they overthrew the independent republics after the War. Apart from its natural difficulties, this journey offered Nansen possibilities of excitement in another form. In the previous year a passenger in the post-car had been stripped and robbed while the mail-carrier at his side had been shot dead, and only a few months before Nansen's trip another passenger had had a bullet through both his knees. As it fared, however, the assurance that the road was now safe from these little attentions from the mountain tribes was justified and the party arrived at Vladikavkas in safety. The danger was very real, for in these remote valleys isolation has preserved the fierce and indomitable character of tribes who held off the Russian arms for so long. As Nansen loosely but graphically says, there are more people of different race and speaking different languages in this small area than in any other spot in the world.

Of the magnificent scenery which once made the Caucasus one of the holiday grounds of the Russian Empire and of the resources of the country the author has given a vivid word picture which he has supplemented with some striking photographs. He notes the remarkable proclivity of the Georgians for building magnificent churches on inaccessible heights, inclining to the explanation that it is an expression of the Persian doctrine that on the lofty holy mountains we are nearer to heaven and to God. He does not incline to the view of that delightful old seventeenth-century traveller, Chardin (whose account of the Georgians has much that is still true to-day), that they chose this situation for their churches " to get out of decorating them or keeping them up, as it was seldom that anyone went there " —a reason which he, at least, considered in full accord with the rest of their actions. He does not appear on the whole to have cared very much for the Georgians.

Nansen was much impressed by the number of different tribes he saw near the military road, and he describes their character and culture at some length. He was also much attracted by their folklore, from which he quotes freely, and institutes a comparison between Scandinavian and Ossete mythology and the paganism beneath the orthodoxy of the latter with its holy groves in which now stand the altar and church. Prometheus still lies chained to Kasbek, the highest peak of the Caucasus, still expiating his sin of stealing fire from heaven for the use of man. Now, the people of the mountains say, he is old, his hair is white, like his beard, which reaches his feet, and his whole body is covered with hair. He is glad to see anyone who comes to him, but anyone who tries to visit him more than once never returns. The old man asks after the present state of the land, whether the young people are taught in the school, and whether the wild fruit trees bear much fruit, and when he is told " no ", he is sorely afflicted.

Nansen was keenly interested in social, political, and economic conditions in Daghestan and discusses them at some length. Daghestan is now one of the Soviet Socialist Republics ; but in religion it is Moslem. The Soviet Government has shown itself unusually tender to this religion ; but, owing to the preponderance of Moslem schools and the administration of justice among Moslems by their own religious officials, apprehension is beginning to be felt lest Moslem influence should become too great. For this there is probably good ground. It makes the situation as interesting to outsiders as it is difficult for the authorities. For the people of Daghestan before the War were said by some, who professed to be competent to judge, to be the most fanatical of all Islam. This is probably an exaggeration; but a country in which thirty-two different languages are spoken by as many and more separate races, and where blood-feud and blood-revenge are widespread, is likely to afford any government a sufficiency of problems without the addition of religious intolerance. The amazing career of Schamyl, a Rob Roy of the Caucasus on a heroic scale, who held back the Russians in a guerrilla war for more than thirty years and only surrendered in 1856, had a fit setting. His career conveys a warning which the Soviet Government is scarcely likely to ignore.

It says much for Nansen's powers of observation and narrative that, after the incidents of the Caucasus, Astrakhan and the Volga with its sturgeon fisheries, though on a lower key, are no anticlimax. The author would surely never have allowed his book to appear without a map. There are few regions for which a map is more necessary.

All who read this book, which is a striking example of the author's powers of observation and quickness in seizing the essentials of a situation, will feel the inevitable pang of regret that this acute and sympathetic intellect will travel no more.

Chemistry through the Ages.

Makers of Chemistry. By Eric John Holmyard. Pp. xvi + 314. (Oxford: Clarendon Press; London: Oxford University Press, 1931.) 7*s.* 6*d.* net.

MANY efforts have been made to assign an origin to alchemy. In less critical and sophisticated ages than ours, individual founders were sought: for example, in Thoth or Hermes; in Muhammad or the Caliph Ali; in Aristotle, Plato, Pythagoras, or Democritus; and in the patriarchs. Thus, Moses, from his convincing manipulation of the golden calf, was elected a member of "this strange chemical society"; Miriam, his sister, was added on account of her supposed invention of the water-bath; Tubal-Cain was welcomed as the metallurgical expert; Cleopatra, a second and rather disturbing woman member, was elected in recognition of her early work on calcium acetate; Jason was admitted as the first gold-maker; Hermes evidently troubled the publication committee with his 36,000 original contributions to chemical literature; "finally", as Dr. Holmyard remarks, "the *Song of Solomon* is an alchemical treatise, and chemistry is so called because it was invented by Noah's son Shem or Chem"! According to this intriguing conceit, Shem may have fitted up the first chemical laboratory in the Ark!

In recent years it has been suggested that alchemy arose in China from the philosophy of Taoism. Dr. Holmyard, however, quotes with approval the belief of von Lippmann, "the greatest living historian of chemistry", that alchemy proper reached China from the west in the eighth century: "in A.D. 714 the first Arab ships dropped anchor at Kanton, and thereafter trade developed with amazing rapidity". Dr. Holmyard casts his vote for "the probable truth of the tradition that chemistry first saw the light in the laboratories of Egyptian priests". Later, at Alexandria, Egyptian practice made effective contact with Greek scientific thought; Greek knowledge and theories were transmitted in turn to Islam; fresh material came in from surrounding countries, including perhaps even India and China; and eventually the accumulated knowledge of the Muslim chemists was disseminated throughout western Europe.

The tenor of these comments will perhaps suggest that Dr. Holmyard's "Makers of Chemistry" is something more than a series of biographical sketches of eminent chemists, such as he presented in his earlier work on "The Great Chemists". The book under notice is, indeed, a history of 'the noble science'; further, it is decidedly the best and brightest of the short histories of chemistry with which the present reviewer is acquainted. A novel point, which strikes the reader at the outset, is that the author has abandoned the customary division into chapters for a more fluid arrangement in a series of 58 sections, of which the following succession (Nos. 12 to 17) is illustrative: neo-Platonism, the fusion of practice with speculation, Zosimos the Panopolitan, a retrospect, the rise of Islam, the origins of alchemy in Islam. This device, blended with a skilful selection of the material, has resulted in a smoothly flowing narrative, seasoned with spirit and colour, which holds the attention from beginning to end. Indeed, it occurs to us that the professional teacher of chemistry (and even the professional student, if the term be admissible) may object that the treatment is too delicate, and that a subject which has so often been handled with a ponderosity proportionate to its importance should not be turned into a light and graceful similitude of a historical novel.

It must not be imagined, however, that Dr. Holmyard has reached so pleasing a result by shirking the primary duties of the historian. On the contrary, the weighing of evidence, the appraising of achievement, the portrayal of personality, the isolation of the salient features of an age, have all been undertaken in a manner worthy of the high reputation of the author. If he relaxes at all from his attitude of rigid and impersonal impartiality, it is when he deals with those former Cinderellas of historical chemistry—the Muslim chemists and the phlogiston theory. Thus, our author says of Razi that he " must be accepted as one of the most remarkable seekers after knowledge that the world has ever seen . . . with the possible exception of his acknowledged master, Jabir, Razi was the most noteworthy intellectual follower of the Greek philosophers that mankind produced for 1900 years after the death of Aristotle ". And here is his eloquent farewell to phlogiston :

" As Priestley's splendid but lonely figure disappears over the horizon, the old theory vanishes for ever. It was a great and brilliant theory, and served chemistry well : the reader will therefore feel a peculiar pleasure in learning that the victors always spoke of it with respect. One of them truly remarked that ' it made chemistry a new science by the precision of its luminous ideas ', and that its simple and easy principles had long been a compass to guide the path of each and every chemist."

Many chemists, however, will continue to hold that although the phlogiston theory—that ' veritable Proteus ' of Lavoisier, which changed its form at every instant—to some extent co-ordinated facts which might otherwise have remained in isolation, yet in the main the notable chemical discoveries of the phlogiston period were made in spite of the theory rather than as a consequence of it.

Roger Bacon is characterised as the epitome of his age rather than as a thinker in advance of it. Paracelsus's chief merit " lies in his emphatic opinion as to the aim of chemistry. . . . The honourable task of the age of iatrochemistry . . . that he inaugurated was to make the way clear for a reasonable medicine ; but it did more—it made the way clear also for a reasonable chemistry." Later, we read of Joseph Black that he " is correctly regarded as one of the greatest chemists of one of the most fruitful periods of chemistry, and his fame rests upon impregnable foundations ".

In discussing the Greek atomists, Dr. Holmyard wisely remarks that " it is fatally easy to read into the views of bygone scientists ideas of a later period ". Thus the superficial resemblance between the classical and modern theories of atomism " very largely vanishes in the light of close inspection ". In other words, each age has its own point of view, which the successful historian must learn to assimilate and understand. " Although Mayow appreciated the necessity of air for combustion, and the similarity between combustion in air and deflagration in nitre, he had no real conception of the true nature of burning or of the composition of the air."

The presentation of the chemical story is enhanced by the author's knack of providing it at intervals with a thumb-nail suggestion of its general historical setting. There is a wealth of illustrations, admirably selected and reproduced. The text, moreover, abounds in quotations from original sources ; these are so illuminating that the chemical reader will possibly regret the omission of the exact references which would allow him to identify them in the originals. Of errors in detail we notice surprisingly few in a work of this amplitude, but it may be remarked that van 't Hoff's space theory (p. 238) dates from 1874, and that it would be preferable to include oxygen in referring to the elementary composition of organic dyes (p. 274).

In concluding, one cannot do better than quote the following reflections upon the position of chemistry a hundred years ago and now :

" The ' makers of chemistry ' — those who fashioned it into the science as we know it—had accomplished their work, and a chemist of 1831 would feel more at home with the chemistry of 1931 than with that of 1781. True, he would be at first bewildered by the multitudes of new compounds, new elements, new reactions, new applications, but he would find the oxygen theory still reigning, the name of Dalton in present reverence, and Avogadro's hypothesis in universal currency. After the first amazement had evaporated he would realise that the basic theories of modern chemistry were the basic theories of his own day ; he would find expansion, extension, modification, but no such revolution as that which was witnessed by the closing years of the eighteenth century. The world has produced chemists of scintillating genius in the nineteenth and twentieth centuries, but their work, marvellous though it be, is but a working out of the principles laid down by Lavoisier, Dalton, and Avogadro." JOHN READ.

Short Reviews.

Textbook of Quantitative Analysis. By Prof. William Thomas Hall. Pp. vii + 279. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1930.) 12*s.* 6*d.* net.

THIS book sets out in detail a course in analytical chemistry for the more advanced grades of intermediate students, who are likely to proceed to a final course in some branch of chemistry. It is based largely on Treadwell and Hall's well-known work, and is complete for the purpose in view so far as inorganic analysis is desired. An introductory course of organic analysis might, we think, have been included with advantage, even at a sacrifice of some of the more specialised portions such as the chapter on steel analysis and tungsten and titanium in ores. Prof. Hall takes the line that it is more advantageous for the student to begin analytical chemistry with volumetric analysis, on the ground that the student is likely to obtain a better view of the subject. This may well be the result in practice, for a volumetric process may be a far more searching test than a gravimetric. A feature of this work is the attention devoted to potentiometric methods. The chapter assigned to this is necessarily a short one in the circumstances, but is nevertheless a desirable addition to a book of more or less elementary character. The volume is free from printing errors, is well got up, and may be commended for its general utility as an intermediate textbook of analytical chemistry.

J. J. F.

La mesure des rayons de courbure des surfaces sphériques employées en optique. Par Albert Arnulf. Pp. 179. (Paris: Éditions de la *Revue d'Optique théorique et instrumentale*, 1930.)

THIS monograph by the director of practical work in the Institute of Optics at Paris gives an excellent account of the theory and practice of the measurement of the radii of spherical surfaces used in optics. The first part deals briefly with the ordinary and dihedral spherometers, their use and errors. The second part, about two-thirds of the book, gives a full account of the method of the dihedron of G. Burch as developed by Fabry, both for workshop and laboratory use, of the method of tangent spheres invented by Fabry, and of interference methods as practised in the laboratory of the Institute of Optics. The remainder of the book deals fully with the autocollimation methods, due originally to Guild, improved by Prytz, and perfected in the Institute, and also gives an account of the various pieces of apparatus built for carrying out these methods.

The book is well illustrated by diagrams and drawings of the apparatus described, and freely supplied with tables giving the results of laboratory experiments and the errors incurred in the various methods. It is extraordinarily complete for its size, and will no doubt prove of the greatest use to those engaged in the measurements indicated and in the construction of the optical apparatus needed.

Faraday. By E. W. Ashcroft. Pp. 134. (London: The British Electrical and Allied Manufacturers Association, 1931.) 7*s.* 6*d.* net.

WITH the forthcoming celebrations of the centenary of the discovery, on Aug. 29, 1831, by Michael Faraday of electromagnetic induction, the interest of scientific workers and of the general public will turn towards the life-story of this remarkable man. His friend and contemporary, Dr. Bence Jones, published a biography, but the time has now come when we can appreciate better the permanent value of Faraday's life and work. Early this year, Mr. Rollo Appleyard issued a brief 'life', and Mr. E. W. Ashcroft has now produced an equally brief survey but of a different type; whereas Mr. Appleyard gave us an intimate view of Faraday, Mr. Ashcroft deals rather with broad aspects of his work and philosophy. He takes successive periods in Faraday's career and endeavours to trace from his writings and from those of his contemporaries, both British and foreign, the growth of his character and work.

As a book, we may criticise the lack of headings to the twenty short chapters and the absence of an index, but we prefer to regard it as an inspiring little souvenir of a great but very human man, whose work marks the inception of an important stage in the progress of civilisation.

Epidemiological Essays. By Dr. F. G. Crookshank. Pp. ix + 136. (London: Kegan Paul and Co., Ltd., 1930.) 7*s.* 6*d.* net.

THIS little book, by a well-known consultant physician interested in epidemiology, consists of ten papers which, with the exception of the essay entitled "Why Times Flies", contributed to *Psyche*, have all been previously published in various medical journals. It may be doubted if some of the papers included were worth saving from the well-merited oblivion which enshrouds most contributions to the medical press; but those interested in the history of medicine and epidemiology are advised to read the essay on the "Trousse-Galants" of 1528–29 and 1545–46, a mysterious disease which seems to have been a severe form of influenza, and that entitled "Some Problems of Influenza", in which the author discusses the periodicity of the disease and the correlation between influenzal prevalences and cosmic and telluric influences.

Introduction to Human Parasitology. By Prof. Asa C. Chandler. Fourth edition, rewritten and enlarged, superseding "Animal Parasites and Human Diseases". Pp. xiv + 655. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1930.) 25*s.* net.

THIS volume is an extended form of an earlier book which was intended for students and the lay public. This larger edition should be more useful to students of biological and medical sciences where an intensive study is not indicated. Its presentation is clear and readable. A short, incomplete account of filterable viruses is included with protozoa, helminths, and arthropods. Only animal parasites are dealt with.

Modern Diving Devices.

By Capt. G. C. C. DAMANT, C.B.E.

THE rubber diving dress evolved by Siebe a hundred years ago extended the useful range of human activities to rather more than a hundred feet below the surface of the sea, and for several years engineers and physiologists have been striving in their respective spheres to double or treble this working depth. Much progress has been made, and as an example of the most advanced methods now in use we reproduce, by courtesy of Messrs. Siebe, Gorman and Co., Ltd., two illustrations (Fig. 1) of the Davis submersible decompression chamber already described in these columns (NATURE, March 15, p. 415; 1930) and to the British Association at its Bristol meeting last year. The diver on finishing his work ascends not to the salvage ship but to this chamber, and, clambering in, finds an attendant waiting to divest him of the helmet and lead weights; the two men close the bottom door, and the chamber, retaining air at any desired pressure, is hoisted on board the salvage ship, which is then free to manœuvre or explode blasting charges while the diver is being slowly decompressed. Within his range the rubber-suited diver will always be supreme, but for objectives still beyond his reach another system is being developed.

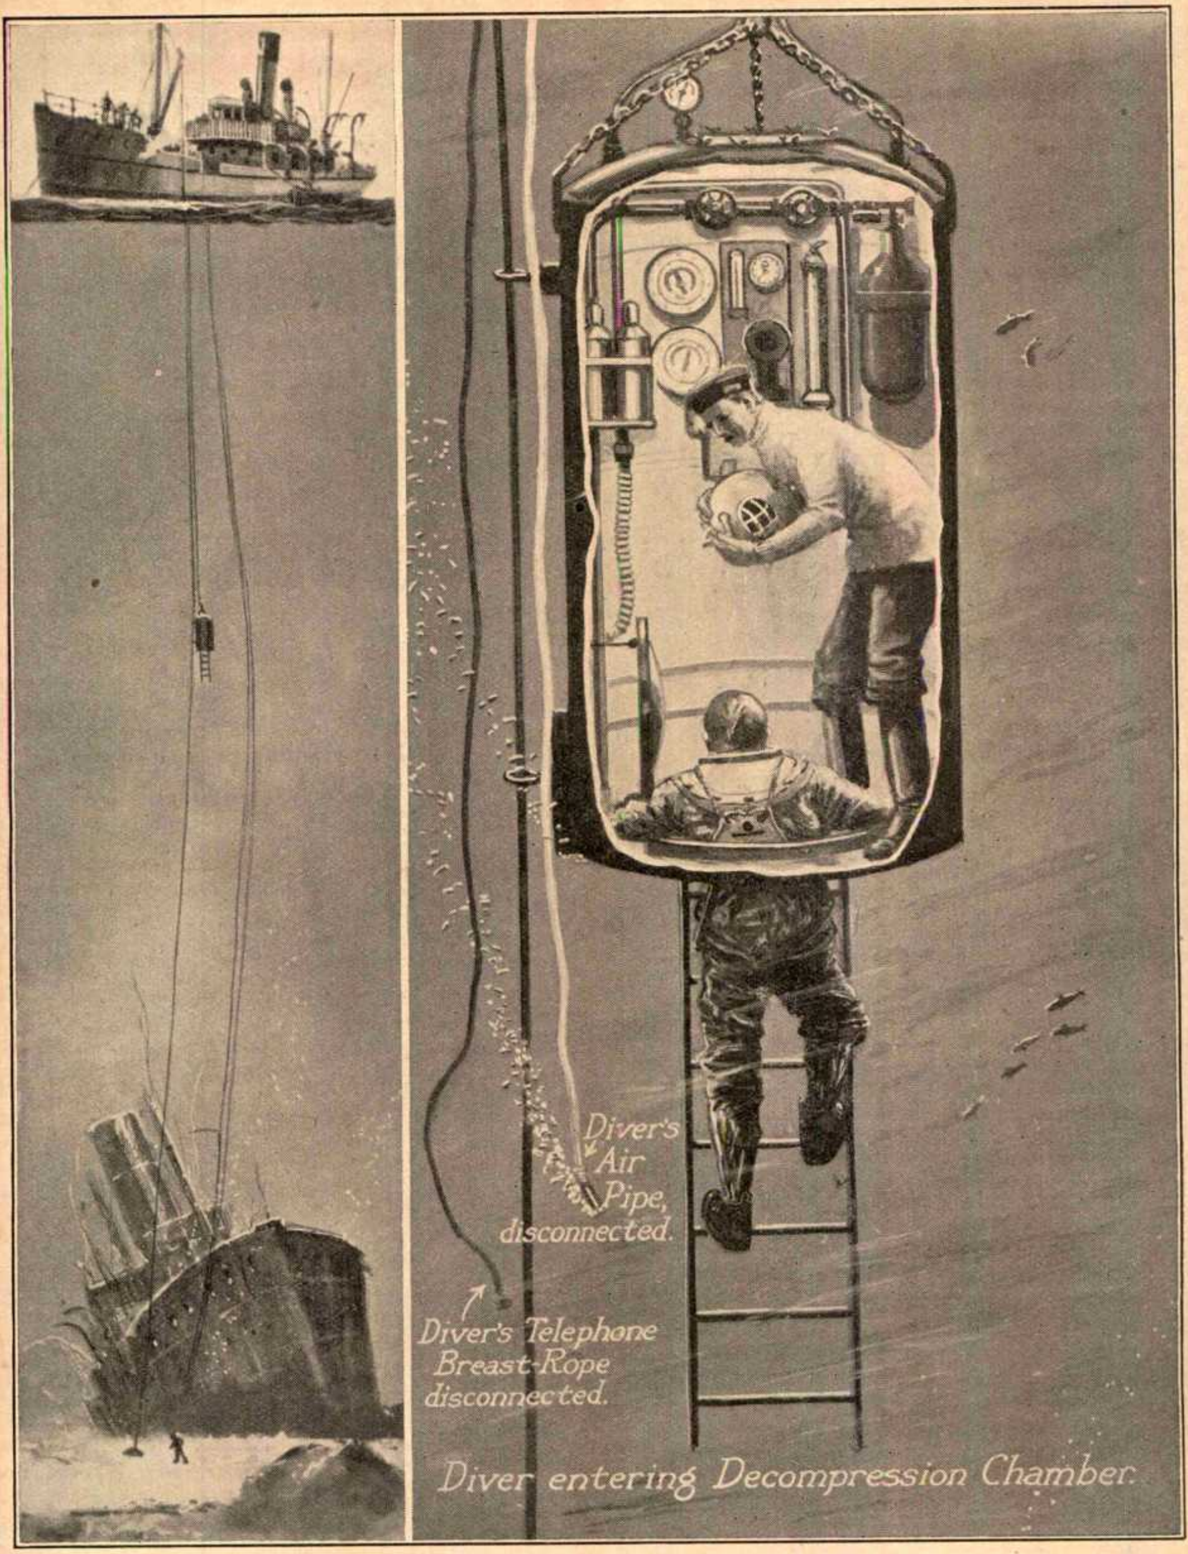
Beebe and Barton (*Bulletin New York Zoological Society*, Nov.-Dec. 1930; see also NATURE, **126**, p. 220, Aug. 9, 1930), wishing to investigate life in the ocean at far greater depths than man had ever attained, adopted a method of admirable simplicity which H. G. Wells had foreseen in one of his early short stories. They constructed a spherical observation chamber (Fig. 2) capable of withstanding the external hydrostatic pressure of 2000 feet of water, furnished it with quartz windows, a telephone, simple apparatus (including two palm leaf fans) for renewing the air vitiated by respiration, and in it they were eventually lowered to a depth of 1400 feet in the sea off Bermuda, where many interesting observations were made. Their 'bathysphere' was a single steel casting 4 ft. 9 in. in diameter and 1½ in. thick; it weighed 2¼ tons in air and ⅞ of a ton when submerged. Beebe, who with his companion spent 1½ hours in it on his principal descent, seems to have been quite comfortable, and writes, "I never realised how much room there was in a sphere four and a half feet in diameter". He found that blackening the interior made it easier to distinguish objects in the dimly lit waters outside, and that something warm and dry to sit on should by no means be forgotten. Since the adventurers were breathing air at atmospheric pressure, no question of compressed air illness arose.

To combine the flexibility of Siebe's dress with the protecting rigidity of Beebe's sphere has been a dream of enthusiasts for at least fifty years, and in 1923 Neufeldt and Kuhnke in Germany produced what at last seemed to be its practical realisation. Their steel dress, nicknamed 'The Iron Man', weighs about 800 lb. in air and has exquisitely constructed joints, watertight yet capable of movement at a depth of 500 feet under an external hydrostatic pressure of 220 lb. per square inch. The diver breathes air at atmospheric pressure, the necessities of respiration being provided for as in the bathysphere. The mechanical tongs in which the arms terminate are well seen in Fig. 3, as well as the telephone cable and steel wire by which the apparatus is raised and lowered.

The inventors soon gave ample demonstration at sea that their apparatus enabled men to descend 400 feet deep in safety, but technical opinion in Great Britain remained unsatisfied that the limbs could be moved with sufficient freedom and the tongs manipulated with sufficient accuracy to do much useful work. However, the Italian salvage company, 'Sorima', of Genoa, took up the invention and exploited it with extraordinary skill and energy in salving the cargoes of ships sunk at great depths during the War. Their remarkable successes, culminating in the location of the famous wreck of the *Egypt* off Ushant, are worthily described in a recent book,[1] the writer of which combines the shrewdest observation with vivid and witty descriptive powers, so that it will be read with lively pleasure by salvage engineers as well as the general public. The former will find it significant that in the hands of the Italian experts the original iron man has undergone a process of involution. At first there were twelve joints, three to each limb; next, the total number of joints was reduced to six; and finally the jointed appendages were cast off altogether, leaving the diver enclosed in a limbless rigid steel shell, where he becomes, as Scott says, "merely the directing brain of the salvage ship, which does its work by machinery under his control".

A limbed suit is still held in reserve, but one infers that, after years of experience, those best qualified to judge have found that the amount of work that can be done by this sort of apparatus does not justify its cost and complication. The observation chamber on which the Sorima now relies differs externally from the bathysphere in being of tapered cylindrical form, and, as a protection in the hurly-burly of salvage work, possessing a buoyancy chamber by which the occupant can cause it to float to the surface in case of breakage of the supporting cable.

It is odd that such a simple method and one requiring so little strength or skill in the diver, has not been used before; often it is desirable for engineers to inspect submerged structures, and many of them, from a sense of duty, have acquired enough of the technique of the rubber suit to be able to go under water, but it is very difficult for anyone not thoroughly practised in diving to make a critical inspection: tides sway the tyro about,



Diver's Air Pipe, disconnected.
Diver's Telephone Breast-Rope disconnected.
Diver entering Decompression Chamber

FIG. 1.—The Davis submersible decompression chamber. On the left, the chamber is slung in mid-water ready for the diver's ascent. On the right, the diver is entering the decompression chamber, which, until the lower door is closed, acts like a diving bell. The attendant has removed the diver's helmet and disconnected his air-pipe and breast rope.

he flounders and, stirring up the mud, obscures his own vision, his breathing is laboured and the discomfort so great that judgment is apt to be hasty; moreover, for elderly men the thing is impossible. The same man in a suitable observation chamber could be travelled by overhead tackle from one end of the work to the other without the least exertion. Beebe was surprised to find what misleading information his nets had been giving about the distribution of the bathypelagic creatures, and it seems certain that under-water observation will sooner or later be used in solving practical fishery problems; it is to be hoped that Great Britain, which used to lead the world in diving, will not be the last to divert some of her marine biologists from determining salinities and measuring herrings to going under water and watching the reactions of fish to the baits on a long line, or even to being towed along in the mouth of a trawl to see what proportion of fish dodge it and how they may be circumvented.

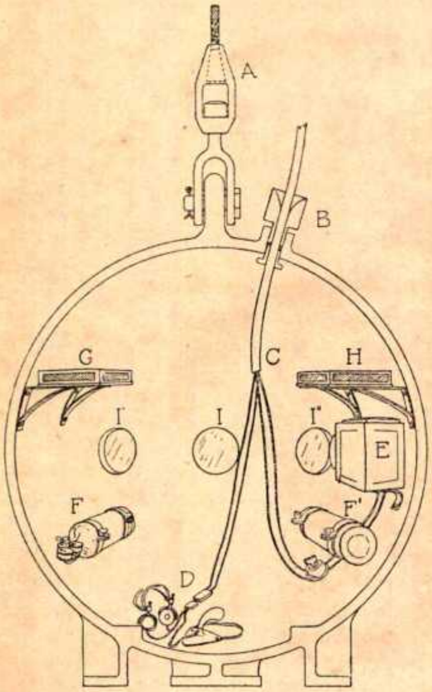


FIG. 2.—Section of the bathysphere. A, swivel for attaching cable to sphere. B, stuffing box through which electric cable enters sphere. C, electric cable, containing two wires for the telephone circuit and two for the electric lights. D, telephone. E, searchlight with beam focused through window I″. F, oxygen tank ready for use with valve attached—one dial showed the amount of oxygen remaining in the tank, the other the rate of discharge. F′, reserve oxygen tank. G, tray containing soda lime for absorbing carbon dioxide. H, tray containing calcium chloride for absorbing moisture. I, main observation window, 6 in. in diameter. I′ and I″, windows for searchlights. The windows were discs of fused quartz 3 in. thick and 8 in. in diameter.—From *Bull. New York Zoo. Soc.*, vol. 33, No. 6. By courtesy of Mr. William Beebe.

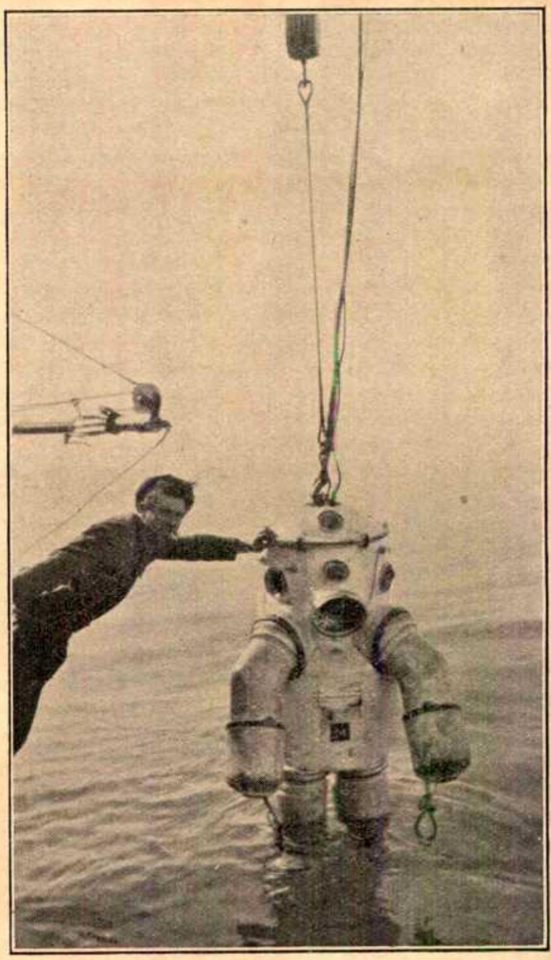

FIG. 3.—Neufeldt and Kuhnke's 'iron man' articulated shell.

Diet and Disease.

REFERENCE has already been made in these columns to certain recent dietary surveys[1, 2]. From such researches it is possible to enlarge our knowledge of the types of diet which different peoples or individuals may find adequate, to point out in what respects diets in common use may fail to satisfy accepted standards, in certain cases to correlate prevalent diseases with a particular type of diet and, by means of additions to the food supply, to confirm the results of the survey and indicate how the diet may most simply be improved. A recent report by Orr and Gilks is of great interest, since the investigators find a marked correlation between diet and physique and general health.[3]

The survey was carried out on two tribes living in Kenya, the A-Kikuyu, who are agriculturists, and the Masai, who are pastoralists. The Kikuyu diet consists chiefly of cereals (maize or millet), tubers, plantains, legumes, and green leaves. Only the women eat green leaves in any quantity; moreover, the consumption of edible earths (salt) is almost confined to them and children up to five years of age. Analysis of the dishes in common use showed that the diet was probably adequate in calories, protein and phosphorus, but low in fat for both sexes. The intake of calcium by the men was definitely subnormal, and probably that of sodium also; the women obtained more of these elements from the green leaves and salt consumed, and their intake of them was probably adequate: some of the edible earths eaten also supplied additional iron.

In contrast to the Akikuyu, the Masai live chiefly on meat, milk, and blood, with small amounts of cereals or fruit. The milk is richer in protein, fat and sugar, than English milk, but poorer in all inorganic constituents except calcium. The diet supplies a large excess of protein and fat, and a liberal supply of mineral elements, but is low in carbohydrate, cellulose, and other indigestible residues. The diet of the women was less extreme than that of the men and approached in composition that of the Kikuyu women.

Physical measurements showed that the Masai men were 5 in. taller and 23 lb. heavier on the average than the Kikuyu men, and the women 3 in. taller and 27 lb. heavier than the Kikuyu women. The Masai are typically larger in the chest and smaller in the abdomen than the Kikuyu. Dynamometer readings showed that the Masai men can exert a hand pressure 30 lb. greater than the Kikuyu; the latter, in fact, are only as strong as the Masai women, but their maximum pressure is about 10 lb. greater than that of their own women.

The incidence of disease was found to be very different in the two tribes. Among the Kikuyu children bone deformities, especially those of late rickets, dental defects, and anæmia were common, but relatively uncommon among the Masai. The incidence of enlarged tonsils and cervical adenitis was the same in both tribes, occurring in about half of the children examined. In the case of the adults, respiratory infections and ulcers were common among the Kikuyu, intestinal stasis and arthritis among the Masai. The Kikuyu women appeared to be less susceptible to disease than the men and were generally in better physical condition.

Some experiments were carried out on native prisoners, on hospital and prison diets, with the object of confirming the inadequacy of the native dietaries, by making additions to the diets and noting any improvements in the retention of different elements or in the composition of the blood. The diets were considered to be inadequate in calcium, and possibly some other inorganic constituents, and in vitamins A and D. The salt supplement was given as a mixture made up to supply in the daily dose approximately the amount of minerals present in 1 pint of milk; the vitamins were supplied in cod liver oil. In adult Kikuyu, it was found that the minerals, especially when given with cod liver oil, increased the calcium retention and also raised the level of the blood calcium, which is lower than that of Europeans at home or in Kenya. With growing Masai boys, it was found that a milk supplement was the most effective in increasing the weight and the calcium retention. The mineral mixture, calcium carbonate and bone flour, also increased the retention of calcium, but cod liver oil had little effect: it appears, therefore, that the chief deficiency in the diets is that of calcium. Bone flour also increased the retention of phosphorus. It was also found that a reformatory diet of maize, potatoes, and beans with ghee and salt did not permit of maximum growth; milk, maize and bone flour and maize supplements increased the growth rate of the boys, milk being the most effective. The diet appeared to be low in energy value as well as in calcium.

Tropical ulcer is common among the Kikuyu but comparatively rare among the Masai. Its incidence could not be correlated with the presence of malaria, syphilis, or intestinal parasites. Although slight injuries appear to precipitate its development, it is difficult to believe that they are the sole cause. The number of cases increases at the end of the dry season. Examination of the blood disclosed the fact that the inorganic phosphorus was very definitely raised in cases of ulcer as compared with other natives or Europeans in Kenya; the serum calcium was about the same in all natives and below the European level. A similar change in the direction of high phosphorus and low calcium occurs in animals on diets containing an excess of the former but deficient in the latter, suggesting that the abnormal ratio between these elements in the native diet is responsible for the change in the composition of the blood; the very high level of the blood phosphorus in ulcer cases, however, is not explained. The evidence certainly suggests that diet plays a large part in the ætiology of ulcer, presumably by decreasing the patient's resistance to trauma. No dramatic healing of ulcers was however produced when additions were made to the diet, although it appeared that they healed more quickly as the patient's general condition improved.

The observers conclude their survey with suggestions for the improvement of the diet of the tribes; both should consume more green vegetables, and the Kikuyu should also drink milk. The preliminary step would be a general improvement in agriculture and animal husbandry, especially among the Kikuyu.

The study is a striking illustration of the fact that man does not invariably select for himself a suitable dietary: it discloses that the incidence of disease among natives may be higher than among more civilised nations, which nevertheless consume 'artificial' rather than 'natural' foodstuffs. Finally, from the varying incidence of different diseases among the two tribes, it suggests that similar diseases among civilised peoples may also have a fundamental dietetic basis.

The Faraday and British Association Centenaries.

THE Royal Institution, the Institution of Electrical Engineers, and the British Association have recently issued programmes of the various events arranged in connexion with the Faraday centenary celebrations and the British Association centenary meetings, being held in London in September. From these, it will be seen that the Faraday centenary celebrations will begin with a reception of the delegates in the Royal Institution on Sept. 21 and conclude with the closing of the Faraday Exhibition on Oct. 3, while the meetings of the British Association will extend over the period Sept. 23–30.

The principal events of the Faraday celebrations will take place, with certain exceptions, on Sept. 21–23. At 11.30 A.M., Sept. 21, an informal meeting will be held in the lecture theatre of the Royal Institution, when an explanation of the programme will be given in English, French, and German, and at 3 P.M. the delegates to the celebrations will be received in the lecture theatre by the president and managers of the Institution. The Faraday commemorative meeting will be held that evening at 8 P.M., in Queen's Hall, Langham Place. W.1. Short speeches will be made by distinguished representatives of institutions in various parts of the world. Music will be given by the Symphony Orchestra of the British Broadcasting Corporation, under the direction of Sir Henry Wood, and the proceedings will be broadcast.

The proceedings of Sept. 22 will begin at 10.30 with a conference of the Institution of Electrical Engineers, to be held at Kingsway Hall, Kingsway, W.C.2. Speakers will include Mr. C. C. Paterson, (president), Mr. Ll. B. Atkinson, Miss C. Haslett, Mr. J. S. Highfield, Sir Oliver Lodge, and Sir Josiah Stamp, the subject for the conference being " The Place of Electricity in the Production and Utilization of Power, and in Transport, Communications, and the Household ". On that evening, at 8.30, conversaziones will be held by both the Royal Institution and the Institution of Electrical Engineers, the conversazione of the latter taking place at the Albert Hall, thus enabling the guests to have a private view of the Faraday Exhibition.

The Faraday Exhibition has been organised by the Institution of Electrical Engineers, assisted by the Royal Institution, in regard to Faraday's original experiments, and by the Federal Council for Chemistry, in relation to chemical discoveries. It will be formally opened to the public at 4.30 on Sept. 23, and will remain open until the evening of Saturday, Oct. 3, the charge for admission being 1*s.* for adults and 6*d.* for children under fourteen. The exhibition is being planned to illustrate the developments of electrical and chemical science and industry in all branches which have followed Faraday's work. Around a statue of Faraday, in the centre of the hall, will be an exhibition of historic apparatus, and from this the exhibits will spread out radially, so that at the outer circumference of the hall will be found the latest examples of electrical apparatus and machinery. There will be nine sections in all, relating to such things as the generation, transmission, and distribution of electric power, electric transport, domestic uses of electricity, and the many branches of electric communication.

In the Albert Hall also, on Sept. 23, at 3 P.M., Lieut.-Gen. the Right Hon. J. C. Smuts will assume the presidency of the British Association, and will receive the invited delegates to the centenary meetings of the Association. At 4.30 P.M., at the invitation of the Institution of Electrical Engineers, he will open the Faraday Exhibition. These will be the inaugural proceedings of the British Association, and in the evening at 9 P.M., in the Central Hall, Westminster, General Smuts will deliver his presidential address.

In addition to these events, the Royal Institution has arranged for a garden party on Sept. 24, at the National Physical Laboratory, by the invitation of the director, Sir Joseph Petavel; and on the evening of Sept. 25, His Majesty's Government will entertain representative delegates and guests to dinner at the Dorchester Hotel, Park Lane. The Prime Minister, Mr. Ramsay Macdonald, hopes to preside. Various visits and excursions are being arranged, and the rooms of the Royal Institution will be at the disposal of delegates and guests from Sept. 12 until Sept. 26.

In connexion with the British Association meetings, a volume is being issued to members, entitled " London and the Advancement of Science ", containing a historical survey of the advancement of science in London through the principal scientific, educational, and State institutions, etc., by various authors ; together with another on " The British Association : a Retrospect, 1831–1931 ", by Mr. O. J. R. Howarth. This is a revised edition of the volume issued in 1922 through the generosity of the late Sir Charles Parsons. It was in 1831, at York, that the Association held its first meeting, and York has been chosen for the meeting in 1932. But an invited party from the Association will pay a visit to its birthplace on Saturday and Sunday, Sept. 26-27, in the middle of the present meeting.

The publications from which these particulars have been taken contain much further information regarding the general arrangements, railway fares, hotel accommodation, passport visas, etc.

Attention may also be directed to a small pamphlet issued by the Metropolitan Borough of Southwark about the Faraday Memorial Library, which was opened in Southwark in 1927. Faraday was born at a house in Newington Butts in the borough, in 1791, and the library, which was established to commemorate his work, now contains some 1800 books devoted to the life and work of Faraday, with text-books and periodical publications of scientific societies. It is maintained by a small endowment fund in the hands of four trustees.

News and Views.

ALTHOUGH it has been exhibited there before, the walrus is sufficiently rare in captivity to make the recent acquisition of two young specimens by the Zoological Gardens at Regent's Park, London, a noteworthy event. Walruses are delicate animals in captivity, perhaps because those that come to land are young, tuskless individuals. It is said that the walrus-cub is suckled by its dam until the tusks appear, so that it may be that the change from the maternal milk diet is at the root of the trouble. At the same time, there is no doubt that some species exhibit innately poor viability in captivity, and that these are sometimes the most robust-looking, and not highly specialised in diet: thus, the gorilla is delicate as well as the walrus, and the capercailzie is the most difficult subject of all the game-birds. The walrus is not only interesting scientifically, but also is a good popular exhibit, for its face exhibits a curiously close caricature of humanity. It would seem, therefore, that Tacitus was playing the arm-chair critic when he cynically suggested ("Annals", ii. 24) that the "marine monsters, forms half-human, half-bestial", told of by returned legionaries of Germanicus after a storm in the North Sea which drove some of them as far as the coasts of Britain, might have been "conjured up by their fears"; for the walrus, which even at the present day occasionally visits our northern coasts, would no doubt have been well in evidence farther south at that date—the early years of the first century of our era. These men also reported "unknown birds", which were also probably not imaginary, as the Great Auk would be equally likely with the walrus to be present and attract attention there and then.

"LIVE and let Live", a plea for the preservation of wild life, is a pamphlet supporting the activities of the newly founded "Association for the Preservation of Game in the United Provinces" of India. Already the Forest Service of the Government has taken a firm stand for the preservation of the wild life within its jurisdiction, but more is required. This new Association is setting out to educate public opinion in the need for the protection of wild life, to encourage the study of natural history in schools and the protection of 'game' in private territories, to check unnecessary slaughter by the public, to co-operate with the Government along similar lines, and, lastly, to create and keep up a national wild game reservation in the United Provinces, where representative Indian animals shall be preserved for all time, and shall be available for the enjoyment and inspection of the people of India. The objects of the Association are worthy of the support of all interested in the preservation of wild life, and the pamphlet, which is signed by Hasan Abid Jafry of Agra and Major J. Corbett of Naini Tal and is countersigned by several Indian and English men of standing, appeals for members and for subscriptions towards the accomplishment of its aims. Contributions should be sent to the Honorary Secretary, Hasan Manzil, Shahgani, Agra, U.P., India.

IN an article in the *Auk* (vol. 48, 1931, p. 22), Dr. Joseph Grinnell, who has done much for the interpretative study of birds in western America, sets out to discuss some problems of the migrations of birds from what he calls a rational point of view. He would shun all notions of mystery and unfathomableness and would attack each problem as if it were a simple thing capable of being "understood eventually in all its details upon the basis of facts discriminately gathered and rationally interpreted". The first batch of results from this inquiry are such as these: that "birds are primordially equipped easily and quickly to cover territory by flight through air" and that "they react in all sorts of ways with exceeding speed and accuracy", fairly obvious conclusions, though the latter in this very general form still requires proof. Dr. Grinnell further deduces that the migration habit in birds is due to a development of ordinary feeding journeys, that it is as easily acquired or discarded as any other habit, and that the factors that induce, maintain, and modify habits of migration are in all likelihood precisely the same as those which control general geographic distribution in all the higher vertebrates.

THIS is travelling pretty far along the line of assumption, reasonable though the assumptions seem to be. Nor does it seem very helpful simply to state that the senses used by birds in finding their way during long seasonal migratory flights are the same as those used in the course of their daily movements. The fact is that Dr. Grinnell, having accepted (curiously enough without proof) the assumption that wonder is inconsistent with rationality, puts the gloss of simplicity over the problems of bird migration. In all probability it is no more accurate to think that when a man wonders he stands with his mouth open and brain paralysed, than it is to assume that simplicity in Nature is necessarily more truthful than complexity and mystery. The fact remains that there is much in the migration of birds that is problematical or mysterious—the best two general books on the subject, English and German, use the word 'problem' in their titles, as Dr. Grinnell does in his—and the scientific approach by way of the analysis of the wonder-arousing phenomenon seems to us to be perfectly legitimate.

IN view of the stories current in the tropics of both hemispheres of dangerous snakes resorting to a spot where a member of their species has been killed, a note in the *Field* of Aug. 8 (p. 218) deserves attention, although appearing over initials (E. P.) only. A milkman of Godalming, it relates, killed a grass snake, measuring 38 inches, and full of eggs, in the road; and, on revisiting the spot next day, found no less than 16 other snakes by the dead one, of which he killed all but two, and was apparently photographed along with them, since a photograph of a young man festooned with snakes of various sizes illustrates the note. He did not, it seems, know what the unfortunate reptiles were or that they were harmless. It is certainly a great pity that, with so limited a wild-life list as ours, such ignorant slaughter should still take place; but the congregation of all these snakes about a dead female, and that a pregnant one, certainly calls for inquiry into its cause.

The presidential address of Sir Henry Miers to the Museums Association at Plymouth, like his former addresses to that body, marks a stage in the progress of museums in Great Britain. It is no exaggeration to say that to Sir Henry himself that progress is almost entirely due. There were strivings in many museums, and many curators were working towards new ideals, but the president of the Museums Association has been instrumental in crystallising rather amorphous efforts and in fixing the stages by which the ideal may be gradually attained. He enumerated some of the gains of the year that has passed. A summer school for the training of curators and assistants was held in London, and this year Edinburgh is to take a share in the instruction. An exhibition was organised in the County Hall, London, to illustrate the manner in which museum specimens and works of art are being distributed by the museums to schools; and a beginning has been made with the allocation of grants-in-aid to various deserving museums from the funds of the Carnegie Trustees. We are at one with him in his praise of the increasing efficiency of the *Museums Journal* under the editorship of Dr. F. A. Bather, and welcome the announcement that the Carnegie Corporation of New York has undertaken to place a sufficient sum at the disposal of the Association for the purposes of an Empire survey of museums. Co-operative sympathy between the museums of the Empire would be for the overwhelming good of all concerned.

The completion of the Saluda Hydro-Electric Station near Columbia in South Carolina shows how the demand for electric power can alter the appearance of a country. When work was first begun on the project in the early part of 1927, the site of the development was an area of gracefully rolling hills, dotted with small farms and homesteads. The population was about four thousand, and there were three churches, six schools, and 193 graveyards in the area which is now inundated to make the largest reservoir in the world. The Saluda dam spans the river and valley for a length of nearly a mile and a half, and is almost a quarter of a mile wide at its base. Along the top of this huge wall of earth a concrete highway forming part of the State roads has been built. Motorists driving along this road have an excellent view of the reservoir, or rather, lake, as it is 41 miles long, 14 miles wide, and has a shore-line of 520 miles. It required more than a year's flow of the river to fill it. In comparison with the dam, the power station, which will have a capacity of 200,000 kilowatts, looks quite small. The Saluda development is a part of the power system of the Associated Gas and Electric Company. The power generated by water turbines is converted into electric power, transmitted at 114 kilovolts, and sold to power companies in South Carolina and neighbouring States. This should ensure the south-eastern part of the United States with an abundant supply of electric power. Photographs of the power station, the transmission lines, and the completed dam are shown in the *Westinghouse International* for August.

In the *G.E.C. Journal* for August there is an interesting paper on discharge tubes and their technical applications, by N. L. Harris and H. G. Jenkins, which shows how rapidly this application of science to industry is developing. Tubes of many types, negative glow, positive column, hot cathode, etc., are now being manufactured. Reservoirs of various gases, including neon, argon, helium, and nitrogen, are connected to the pump system, so that the tube can be filled with any gas required at the required pressure, and direct current and alternating current voltages up to 1000 are available for 'glowing' the tubes. These tubes are used for sound-film recording, picture telegraphy, television, pyrometry, etc. Discharge tubes are also used for protective devices. For example, the Osram earthing lamp can pass 50 amperes for 1/40 sec. without damage. They can also be employed economically for dimming lamps by reducing the applied pressures in lighting circuits. Tubes for rectifying alternating currents are supplied which will give 50 milliamperes at 150 volts. The largest commercial application is the use of neon signs for advertising and decorative lighting. For night flying they are of great use as beacons, landing lines, boundary lights, and obstruction and wind direction indicators. In 1904, Moore introduced long high-voltage tubes filled with carbon dioxide gas at a pressure of about a millimetre of mercury for lighting. These tubes will probably again become popular, as the light they emit is pleasing, and improved technique in manufacture has remedied defects. In 1910, Claude introduced neon tubes for decorative lighting which give a rich red light and the luminous efficiency of which is about double that of the Moore lamps. They are particularly useful for danger signals.

Statistics prove that the use of telephony in large cities is continually increasing. In the statistics, taking into account data up to Jan. 1, 1930, published in *Electrical Communication* for July, we notice that the number of telephones in use per 100 of the population is 4·7 in Liverpool but 8·7 in London, the population in the latter city being seven times greater. In Paris the corresponding number is 12·5, in Berlin 11·9, and in Rome 4·3. In Copenhagen it is 17·3, in Oslo 18·1, and in Stockholm 30·5 or nearly one telephone for every three inhabitants. In New York it is 26·3, in Chicago and Los Angeles about 30, in Seattle and Denver 31·3, in Washington 32·7, and in San Francisco no less than 40·8 telephones for every 100 inhabitants. In the British Dominions, Toronto heads the list with 28·4 telephones for every 100 of the population.

The standard frequency of alternating current supply in Great Britain is fifty cycles per second and electrical engineers are agreed that this frequency should be accurately controlled. Capt. Donaldson, the president-elect of the Institution of Electrical Engineers, has strongly insisted on the importance of having a time-regulated frequency, and this has been done in the case of the extensive system of the North Metropolitan Company, of which he is the chief engineer, for the last three or four years. It has been found possible to operate clocks from the ordinary electric mains of consumers connected to this company's networks. Such clocks can be purchased at prices ranging from three pounds upwards. It is quite possible that these synchronous clocks will gradually supersede hand-wound or hand-regulated clocks.

IN the *Journal of the National Institute of Industrial Psychology* (vol. 5, No. 7) there is a report of a lecture by Mr. Seebohm Rowntree on "Some Industrial Problems of To-day". He pointed out that, when the era of big-scale industry began, Great Britain started with immense advantages, owing to the fact that it had the cheapest coal and iron in the world, the best workmen, machines, mercantile marine, and banking system, with the result that it built up a huge export trade and maintained a higher standard of living than any other country in Europe. Gradually it has been losing ground. Mr. Rowntree attributes this partly to the debasing of currency by our creditors, to our very high real wages, to the money spent on the social services, to the conservativeness and inflexibility of employers and workmen. In the circumstances, he thinks we must either lower our standards or raise our efficiency, or maintain an ever-growing army of unemployed. Of these alternatives he discusses ways in which efficiency might be increased. He thinks that we have made more progress in dealing scientifically with the *material* side of industry than with the *human* side. We have lost in strikes and lock-outs during the last twelve years on the average more than 31 million working days. The nation that first solves the problem of how to induce a man to work as hard in the factory as if he were working for himself is secure in the industrial leadership of the world. As a step in this direction, Mr. Rowntree urges that a right selection of personnel by scientific tests should be made, so that people are assigned to the work for which they are best fitted. A good selection reduces labour turn-over, as well as the cost of training, alleviates monotony, and discloses ability that might otherwise be hidden. Next, the conditions under which the employees work must be good, and this necessitates a study of incentive systems, environmental conditions, etc. The article is suggestive and very interesting, and based on direct experience.

IN the "Summary of Progress of the Geological Survey of Uganda for 1919–1929" (Entebbe, 1931; price 4*s*.), Mr. E. J. Wayland, the director, presents an extremely useful and interesting statement of the knowledge gained during the ten years that have elapsed since his flourishing department was founded. Only a vague idea of Uganda geology was possible in 1919; now there is much to be said about the ten divisions of the geological column that are represented, about the long list of igneous rocks that have been investigated, from the Pre-Cambrian granites to the Tertiary and recent alkali-lavas of Mt. Elgon and the volcanic field of Bufumbiro, and about the tectonics and geological history. Useful minerals and water supply have naturally been given considerable prominence, since the Survey is primarily an economic one, but to geologists the chief interest of Uganda lies in such topics as its past climates, its earth-movements, rift valleys and reversed rivers, and not least in its volcanic activity. Mr. Wayland and his staff have undoubtedly one of the most fascinating countries in the world to investigate, and this admirable report, with the clearly printed provisional geological map which accompanies it, shows how enthusiastically and competently they have attacked the great problems that Uganda offers. Several excellent photographs by Mr. A. D. Combe have been effectively used as illustrations. The officers of the Survey are to be congratulated on a record of achievement of which they may be justly proud.

THE May number of the *Hong Kong Naturalist*, which is issued quarterly and edited by Dr. G. A. C. Herklots and Major H. P. W. Hutson, contains some valuable natural history articles. This is the second part of Volume 2, and in it Major Hutson continues his description of the birds of Hong Kong (Part 6), which is, as before, illustrated by beautiful coloured plates drawn by A. M. Hughes. The present part includes the kingfishers, and there are many species recorded. Not all the kingfishers are fish eaters, and those which live on insects, crabs, frogs, and small reptiles do not show any marked preference for the vicinity of water. Notes on colour, habits, nesting, and field identification make this series a peculiarly happy one. A new series entitled "The Crabs of Hong Kong" (Part 1), by Mr. Chia-Jui Shen, begins in this issue. The introduction gives instructions for collecting, preserving, and shipping, for great care must be taken when handling these often fragile creatures. The Dromiidæ, Raninidæ, Calappidæ, Leucosiidæ, and Parthenopidæ are described, and the work is well illustrated by photographic plates and line drawings. Mr. W. Fowler continues his synopsis of the fishes of China (Part 2), the herrings and related fishes, and an article on fresh-water sponges by Mr. Gist Gee with other smaller papers make up a good number of this interesting magazine.

THE *Proceedings of the California Academy of Sciences*, Fourth Series, vol. 19, No. 13, May 1931, contains the report of the president and that of the director of the Museum and of the Aquarium for the year 1930. One of the latest and most important acquisitions by the Department of Palæontology of the Museum is the large Baldwin collection of molluscs. David Dwight Baldwin was a famous shell collector, the shells being chiefly from the Hawaiian Islands, where he lived and collected for many years. Hawaiian land shells are noted for their beauty, wonderful colouring, and variability, especially the tree and ground snails, and this collection, representing years of individual labour, is unique. Besides collecting, Mr. Baldwin contributed several conchological papers to various scientific journals, including the well-known "Catalogue of the Land and Fresh Water Shells of the Hawaiian Islands". It is well that the Museum should have made this historic and valuable addition to its store, which has now been installed in the Academy's research series.

A REFERENCE to an article of interest to many English naturalists appears in *Svenska Linné-Sällskapets Årsskrift* (Årg. 14, 1931, p. 169). It is a short review of a paper by Dr. Knut Hagberg discussing the influence of Linnæus upon the great author of the "Natural History of Selborne", Gilbert White. The paper itself appeared in *Samf. Nios årsbok Vår tid*, vol. 11, 1930, and it traces the effects of White's correspondence with such disciples of Linnæus as Solander and Sir Joseph Banks. Indeed, in Dr. Hagberg's opinion, the Linnean nature study, through many enthusiastic followers, took a firmer grip in England than in Sweden, and through White's "Selborne" it influenced the poetry of such as Keats, Coleridge, and Wordsworth.

British Birds for August contains two very interesting records from northern Scotland. The first is that of the breeding of the whimbrel (*Numenius phæophus*) in Inverness-shire, and the most gratifying part of A. H. Daukes's description is that the young were allowed to hatch. In all the previous records of the nesting of this rare wader upon the mainland, the clutches of eggs were taken by the self-interested discoverers. The second record is that of the first occurrence in Britain of the red-headed bunting (*Emberiza icterica*) of Asia. The bird was seen in North Ronaldshay, in the Orkney Islands, by Col. G. Eardley Todd, and was shot so that the observation might have "real scientific value"!

IN view of the increased and continued prevalence of cerebro-spinal fever in England and Wales, the Ministry of Health has issued "A Review of Certain Aspects of the Control of Cerebro-Spinal Fever" (*Reps. on Pub. Health and Med. Subjects*, No. 65. London: H.M. Stationery Office. 6d. net.). A survey is given of the present incidence of the disease, the salient clinical, pathological, and bacteriological features, and its infectivity and mode of spread by healthy carriers. Control and treatment are discussed, and in regard to the last-named it is suggested that trial should be given of anti-meningococcus serum, supplies of which are available; and records of such treatment, if employed, are desired by the Ministry.

A LARGE earthquake was recorded at Kew Observatory on Aug. 18. The first impulses at Kew occurred at 14 h. 30 m. 40 s. G.M.T. The records indicate that the disturbance originated about 3800 miles north-east by east of Kew. The epicentre was, therefore, in Northern Mongolia near the great Altai Mountains, and it appears to have been some 400 miles north of that of the very large earthquake which occurred on August 10.

THE Council of the Zoological Society of London has agreed to confer the Society's Silver Medal on Mr. A. St. Alban Smith, in consideration of the very numerous donations he has made to the collection of the Society in 1927, 1928, 1929, and 1930, and of other valuable assistance he has given in Singapore. The actual number of specimens which arrived in London alive from him was 8 in 1927, 33 in 1928, over 200 in 1929, and more than 400 in 1930. They have included binturongs, leopards, a magnificent tiger, a gibbon, tree kangaroos, a number of valuable birds, and a very large number of reptiles, including the largest hamadryad ever seen in captivity, some rare gharials new to the collection, and a number of smaller snakes and lizards.

FOLLOWING the recent exhibition of chemical apparatus in London on July 13–18 in connexion with jubilee celebrations of the Society of Chemical Industry and the Achema exhibitions organised by the Dechema, the German Society for Chemical Apparatus, a similar exhibition in Paris in 1932 is under consideration. The Achema has now received from France, from the Société de Chimie Industrielle, a proposal that these exhibitions should be held alternatively in each of the three countries concerned, an arrangement which would have the advantage not only of avoiding the simultaneous occurrence in different countries of such exhibitions but also of affording opportunities for the mutual study and comparison of the methods of production in the different countries. It is expected that an international exhibition of chemical apparatus and plant will be held in Paris in 1932, followed by a German exhibition (Achema VII.) in Cologne in 1933, and a similar British exhibition in London in 1934.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A head of the building trades department of the Burnley Municipal College—The Director of Education, Education Office, Burnley (Aug. 31). A lecturer in physics and a lecturer in chemistry at the Denbighshire Technical Institute, Wrexham—The Director of Education, Education Offices, Ruthin (Aug. 31). A junior assistant in the pathological department of the Royal East Sussex Hospital, Hastings—The Secretary, Royal East Sussex Hospital, Hastings (Aug. 31). A full-time lecturer in engineering at the Sunderland Technical College—The Chief Education Officer, 15 John Street, Sunderland (Sept. 7). A demonstrator of biology at St. Bartholomew's Hospital Medical College—The Dean, St. Bartholomew's Hospital Medical College, E.C.1 (Sept. 10). A Clement Stephenson entrance scholar at the Royal Veterinary College—The Secretary, Royal Veterinary College, Camden Town, N.W.1. A teacher of mechanical science at the Croydon Central Polytechnic—The Principal, Central Polytechnic, Scarbrook Road, Croydon. An instrument maker and laboratory attendant in the electrical department of the Dundee Technical College and School of Art—The Secretary, Technical College and School of Art, Bell Street, Dundee.

Supplement to NATURE

No. 3226 AUGUST 29, 1931

Faraday and his Contemporaries.

By Engr.-Capt. EDGAR C. SMITH, O.B.E., R.N.

IN the introduction to his " Dissertation on the Progress of the Mathematical and Physical Sciences from 1775 to 1850 ", written during 1852–1854, and published in the eighth edition of the " Encyclopædia Britannica ", J. D. Forbes mentioned as amongst the most eminent workers in physical science during the first quarter of the nineteenth century Young, Malus, Brewster, Fresnel, Arago, Volta, Dalton, Davy, Ørsted, Prevost, Leslie, and Fourier, while among those whose labours belonged to the second quarter of the century he included Faraday, Melloni, Gauss, Sir John Herschel, Poisson, Mitscherlich, Liebig, and Dumas. These were to Forbes some of the outstanding physicists and chemists of his own time, and in the course of his dissertation he reviewed the work of each and gave an estimate of the worth of their achievements.

The position of Forbes as an original investigator, his wide knowledge of contemporary scientific work, his relationship with many of the leaders of science, his judgment and impartiality, give to his summaries a permanent interest, and at the present time, when the centenary of the discovery of electromagnetic induction is being celebrated, it is worth while recalling what Forbes said of Faraday. Having in turn reviewed the work of Galvani, Volta, Davy, Wollaston, Ørsted, Ampère, and Seebeck, Forbes began another section of his history of electricity with the remark, " Immeasurably the larger part of what we know with regard to the nature and laws of electricity and its connexion with magnetism, so far as it has been developed since the discovery of Ørsted, is due to the genius and perseverance of one man—Michael Faraday " ; while later on, when referring to the researches of Faraday as published in the *Philosophical Transactions,* he says, " It would be difficult to name in the history of any progressive experimental subject so large an amount of research prosecuted for so long a time in so methodical a manner and with such remarkable uniformity in plan, and with such unvarying success ". It was with the experiments which led to the discovery of electromagnetic induction that those famous researches began.

Though, when Forbes wrote, Faraday had long been regarded as one of the foremost experimentalists of his age, his reputation had extended far beyond the world of science, and his name had become a household word. In the positions he occupied at the Royal Institution as director of the laboratory and Fullerian professor of chemistry, he became the nation's semi-official exponent of scientific advance, and his lectures rivalled in popularity those previously given by Davy. His great reputation, it is true, was not due to his lectures, but that it was much enhanced thereby there can be no question. For this work he had deliberately and assiduously prepared himself, and his success was unequalled. Men who had no particular interest in science heard him with pleasure, and long afterwards would speak of the impression made on them by his lucid explanations, his unfailing experiments, and his eloquence. When at the height of his powers, he was not only a man of science of international repute, but also a prominent figure in the life of the nation, and as such occupies a place in history beside his contemporaries, Dickens, Thackeray, Ruskin, Carlyle, Mill, and Huxley, as one of the intellectual leaders of his age. Of his private life and character much has been written, but as Sir William Bragg has said, "It is Faraday's public life that belongs to us; it is one of the possessions of the nation, one of the great treasures".

Faraday was born in London on Sept. 22, 1791, in the middle of the reign of George II., and died at Hampton Court on Aug. 25, 1867, in the thirtieth year of the reign of Victoria. His life therefore covered a period of vast social and economic development. He was a bookseller's apprentice when Trafalgar was fought; a young man of twenty-four when Waterloo was won. His first journeys were by coach; his first voyages made under sail; the first books he read were printed by hand. Within his lifetime England was covered by a network of railways; steamships found their way into every sea; while books and newspapers were brought within the reach of all. Industries, manufactures, and commerce multiplied apace, and transport and communication were revolutionised. His was indeed an age of great men and great enterprises.

Faraday's own original work, however, done within the quiet of the laboratory, was of a different order from that of the Stephensons and the Brunels. Neither was it of a kind to attract widespread interest. Nothing he ever did took the world by storm as did the discovery of Neptune by Leverrier and Adams; nothing he ever wrote raised such controversies as the works of Darwin and Huxley. It was of the same character as that of Lavoisier and of Joule, and it has proved to be of the same fundamental importance.

Faraday first gained distinction as a chemist. His first contribution to scientific literature was a chemical paper; he is known to every chemist as the discoverer of benzene; he was offered the chair of chemistry in the newly founded University of London; he counted many of the greatest chemists as his friends; a chemist delivered his *éloge* before the Paris Academy of Sciences, and his name is perpetuated by the Faraday Lecture of the Chemical Society. His earliest knowledge of the subject he gained when a boy from the "Conversations on Chemistry" of Mrs. Marcet, the wife of a Swiss doctor. In after life he came to know Mrs. Marcet and, after her death in 1858, in writing to Auguste de la Rive at Geneva, he referred to his debt to her.

The story of how Faraday's studies led to his being given a ticket to Davy's lectures at the Royal Institution, of how he appealed to Davy for employment, and of how he became Davy's assistant and accompanied him and Lady Davy to the Continent in 1813 is well known. The long visit to France, Switzerland, and Italy made a great impression on Faraday and, as Ostwald said, it proved for him a high school of incomparable value. Brewster also visited the Continent in 1814, as did Mrs. Somerville in 1816, and in their biographies, as in those of Davy and Faraday, are to be found much of interest regarding the scientific circles into which Faraday gained an insight. One outcome of the journey was the friendship of Faraday with the elder De la Rive, of whom Faraday once wrote, "I may say he was the first who, personally at Geneva and afterwards by correspondence, encouraged, and by that sustained me".

Returning home with Davy in 1815, Faraday was re-engaged by the Managers of the Royal Institution and was thus brought into contact with Davy's successor, Brande. Described as "a model lecturer, gentlemanly, perfect of expression, exact of execution", Brande occupied a high position in both scientific and official circles, but his vocation when lecturing with the assistance of Faraday was pronounced to be "lecturing on velvet".

Among the most eminent chemists whom Faraday counted his friends were Graham, Liebig, Schönbein, Sainte-Claire-Deville, and Dumas. The correspondence of Faraday and Schönbein has been published in a separate volume, while among the letters from Liebig is that written from Giessen in 1844, in which Liebig openly expressed his admiration, affection, and esteem for Faraday. None esteemed Faraday's friendship more highly than Dumas, who when delivering his *éloge* on Faraday to the Paris Academy of Sciences, began with the sentence, "Je ne sais s'il existe au monde un savant qui ne fût heureux de laisser en mourant des travaux pareils à ceux dont Faraday a fait jouir ses contemporains et qu'il a légués à la postérité; mais je suis sûr que tous ceux qui l'ont connu voudraient approcher de cette perfection morale qu'il atteignait sans effort".

It was but natural that Faraday's first work should be in the realm of chemistry, but as Tyndall said, he was "swerving incessantly from chemistry into physics", and it was as a physicist he gained his great fame. Just as he had obtained his first information on chemistry from the pages of Mrs. Marcet, so while still an apprentice he gleaned his first knowledge of electricity from the pages of the "Encyclopædia Britannica". There, no doubt, he read of the experiments of Gilbert, Boyle, and Newton; of the electric machine of Otto von Guericke; of the lectures of Hauksbee; of the experiments of Stephen Gray in the Charterhouse;

of the invention of the Leyden jar, and of that " auspicious period when Dr. Franklin raised electricity to the dignity of a science, and connected it with that tremendous agency which had so often terrified the moral and convulsed the physical world ".

No branch of experimental science was more actively pursued during the eighteenth century than that of electricity. In Italy, in Germany, in France, and in England, thousands of experiments were made, and to the latter half of the century belong the labours of Coulomb, Aepinus, Priestley, Canton, Watson, Beccaria, Galvani, and Volta. Faraday was born in the year that Galvani wrote his memoir, " De viribus electricitatis in moto musculari commentarius " ; he was a boy of nine when Volta described his pile to Sir Joseph Banks. Yet in spite of all these advances, when Faraday was poring over the pages of the " Encyclopædia ", the sciences of electricity and magnetism were still unconnected, and it was not until 1820 that Ørsted at Copenhagen made known his epoch-making discovery of electromagnetism. Eagerly seized on by a score of investigators in all parts of Europe, Ørsted's experiments were quickly repeated and extended, and on Christmas Day 1821 Faraday called his young wife into the laboratory at the Royal Institution to show her a magnetic needle rotating around a wire carrying an electric current. That experiment was the direct outcome of Ørsted's discovery that by an electric current magnetism could be produced. Ten years later, Faraday himself set up another landmark in the history of electricity by showing how magnetism could be used to generate currents.

During the eleven years which elapsed between the discovery of electromagnetism and that of electromagnetic induction, Faraday was largely occupied with his researches on the condensation of gases, the alloys of steel, the compounds of hydrogen and carbon, and the manufacture of glass. But the new science of electromagnetism was developed in many laboratories. De la Rive in Switzerland was the first to give a public demonstration of Ørsted's experiment. In Paris in 1820, Arago, Savart, and Biot all began to work on electromagnetism, and in the same year, at Halle, Schweigger made the first galvanometer. Of especial importance was the work of Ampère, ' the Newton of electricity ', whose " Exposé des nouvelles découvertes sur l'Électricité et le Magnétisme de MM. Ørsted, Arago, Ampère, H. Davy, Biot, Erman, Schweigger, De la Rive, etc.", published in 1822, contained an account of his own researches as well as of those of his contemporaries. In 1824, Arago observed the damping effect of a plate of copper on an oscillating magnetic needle; in 1825, Sir John Herschel and Babbage caused a pivoted copper disc to move by spinning a magnet near it; and the same year, Sturgeon, the ex-artilleryman, presented the first electromagnet ever made to the Royal Society of Arts, and, as Silvanus Thompson said, thus furnished mankind " with a magnet the attractive power of which could be increased absolutely indefinitely by the mere expenditure of sufficient capital upon the iron core and its surrounding copper coils and the provision of a sufficiently powerful source of electric current to excite the magnetisation ". Two years later, Ohm, then on leave in Berlin, published " Die galvanische Kette, mathematisch bearbeitet " ; and in 1829, on the other side of the Atlantic, Henry, of Albany, " the first to undertake important original electrical experimentation in the United States since the time of Franklin", made his famous electromagnet capable of sustaining fifty times its own weight, which had 400 turns of silk-covered copper wire.

It was therefore no unsurveyed territory, no untrodden country that Faraday re-entered in the summer of 1831. He was but one of many pioneers who were advancing along different paths into this fruitful domain of electromagnetism. " In the history of discovery ", said Emerson, " the ripe and latent truth seems to have fashioned a brain for itself." The latent truth we associate with the name of Faraday is that of electromagnetic induction, the discovery of which was made with the historic iron ring wound with two separate coils of copper wire, and which is recorded in his diary on Aug. 29, 1831. But just as the theory of gravitation had simultaneously occupied the minds of Hooke, Halley, and Wren, as well as that of Newton, so electromagnetism was being studied by others than Faraday, and the observations on the production of an electric current by a magnet by Zantedeschi and Henry actually preceded that of Faraday. Francesco Zantedeschi, the Italian priest and physicist of Venice, it is claimed, published papers on the production of electric currents in closed circuits by the approach and withdrawal of magnets in 1829 and 1830, and Henry in August 1830, by sending a momentary current through the coils of one of his electromagnets, detected a current in a wire wound around the armature of the magnet. But Henry failed to make known his observation or to follow it up immediately.

In commemorating the centenary of Faraday's discovery, however, the world is commemorating not a single and isolated experiment but one which marked the commencement of that long and remarkable series of investigations which occupied Faraday for a quarter of a century, and an account of which is given in his "Experimental Researches in Electricity". The experiment of Aug. 29 was but the key to a Temple of Science as vast as that Temple of Art of which Lafcadio Hearn wrote in one of his letters: "The more you advance the more seemingly infinite becomes the vastness of the place, the more interminable its vistas of arches and the more mysterious its endless succession of aisles".

Having thus found the key, Faraday immediately began to explore further, and with remarkable success. "In ten days of actual work during the autumn months of 1831", as Sir Ambrose Fleming has said, "Faraday not only discovered the facts of current induction and magneto-electric induction as well, but embraced them all in the statement of one great generalisation of the utmost simplicity".

These researches alone led finally to the invention of the magneto-electric machine, the induction coil, the dynamo, and the transformer, but they were succeeded in the course of years by his electrostatic investigations and researches on specific inductive capacity, by his electrochemical researches and researches on voltaic action, and by his researches on magnetism and light; investigations which have engaged the attention of the most eminent physicists of nearly a century, and on some of which has been based that extended application of electricity to man's use we see around us to-day.

In the prosecution of these investigations, Faraday utilised every resource provided by his forerunners and his contemporaries, and his results he placed unreservedly at the service of his fellows. There are many aspects of his work in relation to that of his contemporaries which invite consideration, but to one only can reference be made here. The discovery of electromagnetic induction may be compared with that of the discovery of the pressure of the atmosphere. From the latter came the steam engine; from the former the dynamo. But just as half a century elapsed between the observation of Torricelli and the work of Huygens, Papin, Savery, and Newcomen, so more than thirty years passed before the discovery of Faraday was applied to the self-exciting electric generators of Varley, Ladd, Wheatstone, and Werner Siemens, to which the last gave the name dynamo-electric machines.

Many inventors like Pixii, Dal Negro, Saxton, Clarke, and Jacobi had made small magneto-electric machines in the early 'thirties; the induction coil was developed by Page and Ruhmkorff, and experiments were made with lighting by electricity generated by magneto-electric machines. But interesting as was the work done with these machines, when Forbes wrote, they were still regarded mainly as instruments for the laboratory, and the most important source of electricity was still the voltaic cell, the invention of which Forbes compared to that of the steam engine. From the invention of Volta and the discovery of Ørsted had come the use of electricity for signalling, and the grand achievement of the electricians of Faraday's lifetime was the electric telegraph. Gauss, Weber, Steinheil, Wheatstone, Cooke, and Morse were all contemporaries of Faraday, and it was they who laid the foundations of the great telegraph systems of the world. Five years before Faraday died, it was estimated that Great Britain had 15,000 miles of electric telegraph, Europe 80,000 miles, and America 45,000 miles. But no one had yet dreamed of the generation, transmission, and utilisation of electricity on a large scale. Even Faraday himself failed to see what his own child would grow into, and just as Watt would have nothing to do with the steam locomotive and the steam boat, so Faraday set down the magneto-electric engine along with mesmerism, odylism, the sympathetic compass, and perpetual motion as an ill weed which should not be cultivated.

Nevertheless, gradually, step by step, the difficulties were being solved, and with the work of Pacinotti, Wilde, Varley, Wheatstone, and Siemens a new chapter was opened in the history of the application of electricity. In the retirement of his home on Hampton Court Green, Faraday heard with interest of Wilde's machine, but when the dynamos of Wheatstone and Werner Siemens were described to the Royal Society, both his physical and mental powers were rapidly waning, and a few months later he passed away.

Nearly a century before Faraday died, Boswell had visited the famous steam engine factory of Boulton and Watt at Soho, and Boulton had proudly exclaimed to him, "I sell here, sir, what all the world desires to have—POWER". The demand of the world for power has been an ever-increasing one, and a multitude of discoverers, inventors, and engineers have contributed towards the satisfaction of that demand. Some live in history, some are forgotten, but among those whose names are imperishable is Michael Faraday.

Faraday and Ørsted.

By Mrs. Kirstine Meyer, Copenhagen.

ØRSTED'S discovery of electromagnetism came as a surprise to the scientific world and apparently without any preparatory work. It was communicated in a paper (July 1820), which in the briefest form possible gave an account of the conditions under which the experiments were made and of their results. His results have proved to be correct, but there are no drawings, no indications of the series of experiments he made,[1] or rather of the several series of experiments, to indicate the way these results were reached. It has been said that the whole discovery was due to chance; that was far from being the case. Ørsted had for years been seeking a connexion between electricity and magnetism, and the discovery was the result of his search.

The chief contents of the communication are as follows:

The electric current—in Ørsted's language, "the electrical conflict" in the conductor—acts on a magnetic needle; the direction of the force is sideways and outwards from the conductor, and it has been found in, one might almost say, every possible position of the conductor in relation to the magnet. A simple rule is given for finding the direction of the force. It is shown that the action of the force does not depend on the intermediate substance between the magnet and the conductor. The magnitude of the force is found to depend on the distance from the magnet, the power of the battery, and the quality of the connecting conductor. He also noticed that a circuit in the form of a polygon carrying an electric current attracts or repels the pole of a magnet. Finally, quite briefly, attention is directed to the fact that "the electrical conflict", judging from these experiments, is not restricted to the conductor, but is communicated to the surrounding space, and must be assumed to traverse circles the planes of which are at right angles to the conductor.

The experiments were extended and the results were published soon after, under the title "Neuere elektromagnetische Versuche", in the July number (1821) of *Schweiggers Journal für Chemie und Physik*. This work was evidently finished shortly after the first and should be regarded as coherent with it, as it forms an important supplement to it. It contains the following results:

(1) The effect of a conducting wire on the pole of a magnet depends on the quantity of electricity and not on its tension—in modern words, on the current and not on the electromotive force of the supply.

(2) The reaction effect is found by showing that a suspended closed circuit is turned by a magnet.

(3) It is established in a new way that a closed circuit has a north end and a south end just like a magnet.

From the moment that Ørsted's discovery became known, it created an enormous sensation. The results communicated were so astounding that they were received with a certain distrust, but they were stated with such accuracy that it was scarcely possible to entertain doubts. The treatise itself was thus a strong inducement to put the results to a test; as Ørsted had given no real description of his procedure, scientific workers made the experiments in a variety of ways. Many of those who repeated Ørsted's experiments were thus led to consider themselves and others to be Ørsted's equals in this field of research, and published their work as new discoveries, even if their results were in reality to be found in Ørsted's communication. The language of the latter also caused difficulty, and was responsible for the imperfect comprehension of its contents.

All were soon imbued with the excessive importance of the discovery, and the scientific journals were filled with electromagnetical essays. In England, too, the discovery received full credit. In 1821, Faraday wrote a historical survey of the evolution of electromagnetism up to April 1821.[2] Though only eight months had passed since Ørsted's communication, so much had already been written that Faraday found it very difficult to make head or tail of the many works, of what had been done and by whom, "in consequence of their great variety, the number of theories advanced in them, their confused dates, and other circumstances".[3] He then undertook to go through systematically, "with great labour and fatigue", everything that had appeared in journals and other places. He gives full credit to Ørsted's work; about the first communication he writes: "It is full of important matter, and contains, in few words, the results of a great number of observations; and, with his second paper, comprises a very large part of the facts, that are as yet known relating to the subject". He acknowledges Ørsted's discovery to be not only a lucky chance but also the fruit of a deliberate search: "Mr. Ørsted . . . has for many years been engaged in inquiries respecting the identity of chemical, electrical, and magnetic forces . . . his constancy in the pursuit of his subject, both by reasoning and experiment, was well rewarded in the winter of 1819–20 by the discovery of a fact of which not a single person beside himself had the slightest suspicion ; but which, when once known, instantly drew the attention of all those who were at all able to appreciate its importance and value ".

Faraday repeated almost all the experiments Ørsted described, and this led him in the beginning of September 1821 to discover a method of producing a continuous rotation of a wire with an electrical current round a magnet and of a magnet round the wire. Although the fact of the tangenial force between an electric current and a magnetic pole was clearly stated by Ørsted and clearly apprehended by Ampère and others, the realisation of the continuous rotation of the wire and the magnet required ingenuity for its original solution.

This article of Faraday's, containing his first work on electromagnetic problems, forced on his mind the facts that an electrical current and a magnet act on one another with forces which could create continuous rotations, that a closed electrical circuit could act as a magnet with a north pole and a south pole, that an electrical current could magnetise iron, and that all these results had been observed because Ørsted "had for many years been engaged on inquiries respecting the identity of chemical, electrical, and magnetic forces ".

From this time on, Faraday applied the full force of his mind to certain problems arising out of these results, and he kept them persistently in view even when, year after year, his attempts to solve them were unsuccessful. One of these problems was : "Convert magnetism in electricity ", as he writes in his note-book in 1822 ; he solved the problem in 1831. Another problem was to find a relationship between electricity and magnetism and light. In 1845 he found that magnetism exerts an influence on light.

The philosophical problem, the correlation of physical forces, interested Faraday as well as Ørsted. In the year 1834, Faraday gave a course of six lectures on "The Mutual Action of Electrical and Chemical Phenomena; . . . Relations of Chemical Affinity, Electricity, Heat, Magnetism and other powers of Matter ". In the last lecture he gives his first utterance on the correlation of physical forces : "Now consider a little more generally the relation of all these powers. We cannot say that any one is the cause of the others, but only that all are connected and due to one common cause." . . .

While the philosophical views of Faraday and Ørsted thus present similarities, a marked difference is also exhibited. In his youth, Ørsted had been strongly influenced by the German *Naturphilosophie* and was thereby led to accept too uncritically theories which rested only on speculation and had no sufficient experimental verification. Although through his experimental work Ørsted's connexion with this philosophy was gradually weakened, he was never so sceptical towards theoretical speculation as Faraday, whose critical mind is typically expressed in his attitude to the electromagnetic theory of Ampère ; nor, of course, was Ørsted so ingenious in seeking for experimental verification of theories as Faraday. The truth of the points here emphasised appears also clearly from the contributions of these two men in quite a different field of research.

The first important experimental work from the hand of Ørsted was among the publications of the Royal Danish Society of Sciences for the year 1807, and bore the title "Forsøg over Klangfigurer " (Experiments on Acoustical Figures). Influenced by his ideas about the universal importance of electricity in physical phenomena, he expected to discover electrical effects due to the oscillations causing the acoustical figures. The paper was based on several hundred experiments on acoustical figures produced on square plates of glass or metal, a few of them on circular plates. While Chladni used sand to make the acoustical figures visible, Ørsted employed lycopodium in most of his experiments, and with this fine powder the figures showed somewhat differently. He did not find electrical effects, but he became aware of certain phenomena which he supposed might afford an important insight into the mechanism of the production of a tone, and hence the treatise gives an account of the many experiments carried out in order to clear up this matter. A series of minor motions in the plate are revealed by the lycopodium ; in particular it is remarkable that small heaps of lycopodium accumulate where the vibration is greatest. He sets forth the idea that these minor motions show that every sonorous oscillation is composed of a number of minor oscillations. "Hence the nature of each tone seems to be more dependent on the relation between the subordinate oscillations and the main oscillation than on the mere number of main oscillations. Each tone thus seems an organisation of oscillations."

Savart took up the same investigation about

M Faraday

twenty years later; he came to the same conclusions as Ørsted and explained them in a similar way, it being his opinion that the minor oscillations offer information about the overtones that determine the timbre of the plate.

Faraday took up the question for definite determination in 1831. He only mentions Ørsted's paper, his attention having been directed to the subject by Savart's paper. By a wonderful series of experiments he shows that the accumulation of light dust in certain places does not mean any secondary division of the plate according to overtones, but is only due to currents of air passing over the plate in motion.

In 1846 Ørsted visited Faraday's laboratory, and his interest was especially aroused by the great electromagnet which Faraday had used in his famous investigations on diamagnetism in 1845. Faraday demonstrated the results of these researches before Ørsted, who became so interested in them that on his return to Copenhagen he had a powerful electromagnet constructed and started an investigation on diamagnetic phenomena, the result of which was published in 1848. In consequence of these observations, Ørsted divided all bodies magnetically into three groups: those repelled and diamagnetic, those attracted and diamagnetic, and those that behave like iron. This division answers to that introduced in modern times: the diamagnetic, the paramagnetic, and the ferromagnetic.

Faraday's discovery of diamagnetism was thus the direct cause of the last published experimental work of Ørsted, but Faraday's activity had another influence on Ørsted which became of vital importance for the rest of his life. When Ørsted in 1823 visited England at the end of a longer journey, his work as a man of science received general recognition; in Paris he had received the mathematical prize of the Academy of Sciences, and in London he was elected a foreign member of the Royal Society. It might then have been expected that on his return he would devote himself entirely to the scientific investigations which he had started already. His visit to the Royal Institution, where Faraday was working, changed these plans. The object of the Royal Institution was to diffuse a knowledge of useful mechanical improvements and to promote the application of science to daily life. The manner in which this object was realised through the activities of Faraday made so strong an impression on Ørsted that he on his return founded a society in Copenhagen with similar aims. This society has had an important although indirect influence on the progress of the Danish community, and also on Ørsted himself, for it directed him away from purely scientific work to a large and unselfish activity in the education of his nation.

It is interesting to see that the character of the two men was evidently of the same type. It has been said of Faraday that he was entirely free from pride and undue self-assertion, and that in his old age he remained content and happy in the exercise of those kindly feelings and warm affections which he had cultivated no less carefully than his scientific power. The same could be said of Ørsted. A Danish poet, a friend of Ørsted, has said that he possessed what one might call a high degree of " mental innocence " and always thought that " everybody was guided by the same interest for science, by the same sense of justice and reason as he himself "; he thought that one who knows how to deal wisely and correctly will do so. One has the same impression of Faraday from his life and from his letters. Each man worked conscientiously and unselfishly for the community in which he lived.

Gauss's Investigations on Electrodynamics.

By Dr. CLEMENS SCHAEFER,
Professor of Experimental Physics, and Director of the Physical Institute, University of Breslau.*

THE greatness of the life-work of an investigator is revealed most clearly, perhaps, when we contemplate his influence on the scientific work of his contemporaries. I propose to endeavour to show the influence exerted by Faraday's discovery of electromagnetic induction on the physical investigations of C. F. Gauss, *princeps mathematicorum.*[1]

Even in his youth Gauss was interested in physical problems, and we possess documentary evidence that, in the year 1806, he had already completed his theory of terrestrial magnetism, although it did not appear until 1839. As is well known, the theoretical nucleus of this theory consists of the development of the magnetic potential of the earth's field in spherical functions, the coefficients

* Translated by Dr. R. W. Lawson.

of which have to be determined empirically. Lack of observational data delayed the completion of this work by more than thirty years, and other physical investigations of Gauss suffered the same fate. Not until about the year 1830 did Gauss again turn his attention to physical investigations.

Meanwhile, however, the situation in science had been completely transformed, as the following statements will serve to show. Electromagnetism was discovered by Ørsted in 1820; in 1820–21, Biot and Savart formulated their fundamental law on the force exerted between a magnetic pole and a current element; and this was followed in 1822–24 by the fundamental researches of Ampère on the replaceability by a magnetic shell of a conductor bearing a current, and the establishment of Ampère's law. Then, in the year 1827, G. S. Ohm established his law of the galvanic circuit; in 1828, Green (Nottingham) published his paper on the theory of potential, which, incidentally, remained unknown to Gauss; and finally, in the year 1831, Faraday discovered induction, the counterpart of electromagnetism. The scientific situation was thus fundamentally changed when, in 1830, Wilhelm Weber was called to Gottingen as professor of experimental physics; and at this juncture, on these well-constructed foundations, Gauss's physical researches commenced.

Gauss's investigations were concerned first with terrestrial magnetism, and he showed us how to measure the earth's field exactly; at the same time, he originated the absolute system of units. But the general foundations had scarcely been developed by him, in conjunction with Weber, before he began to give attention also to the study of electrodynamics. On Oct. 22, 1832, Gauss carried out electromagnetic measurements for the first time, and these occupied him during succeeding years until about 1836. Although investigations on Ohm's law, due in particular to Fechner, were available even in the year 1832, they did not satisfy the high standard of attainment demanded by Gauss. Thus his first measurements were directed to testing Ohm's law under the most varied conditions. In this connexion (1833) Gauss discovered the laws of branched circuits, which to-day are known as Kirchhoff's laws, although Kirchhoff did not discover them until the year 1845. Gauss also found out the principle of minimum heat—which was likewise rediscovered later (1848) by Kirchhoff—according to which the heat produced by the current is a minimum for the actual current distribution. Furthermore, he supplied the exact proof of the identity of frictional electricity and that produced by galvanic elements and thermoelectric forces, of which identity by no means all physicists were at that time convinced. However, these were only the preliminary studies.

His chief interest was concentrated on the investigation of the laws of induction. The year 1834 resulted in the construction of an induction coil, and enabled him to recognise the damping of a magnet vibrating in a coil, as a consequence of the induced currents; this led him to the construction of a copper damper for his magnetic apparatus, and to the discovery of the phenomenon of 'sympathetic vibrations'. His work reached its zenith in the year 1835, for on Jan. 23 of that year [2] he formulated the law of induction, which is to-day designated the 'Franz Neumann law of potential', although Neumann formulated it ten years later, in 1845.

We will now pass on to the narration of this crowning accomplishment. The train of thought which guided Gauss was as follows: When a current-free conductor is moved relatively to a current-bearing conductor, a current is set up also in the first conductor, the induced current; at the same time, however, there are established between the two current conductors electrodynamic forces, which obey Ampère's basal law. The latter law is thus most intimately related to the phenomenon of induction. For this reason Gauss first took up the detailed study of Ampère's law, and immediately recognised that there can be added to the mathematical expression for the forces, differential expressions of such a nature that they vanish when integrated over closed current circuits. We can thus replace this elementary law by an infinite number of equivalent laws. By effecting various transformations of this kind on Ampère's law, Gauss also arrived at a law which was formulated ten years later (1845) by Grassmann, and differs in its outward form quite substantially from the fundamental law of Ampère. In fact, Grassmann did not recognise that his law was wholly equivalent to that of Ampère, and he proposed experiments to decide between the two laws, whereas Gauss perceived from the first that there cannot exist any *experimentum crucis* between the two, if only closed currents are available.[3] Gauss laid no great value on the formulation of Grassmann's law, evidently because he recognised that it contradicts the law of action and reaction for current elements, whereas Ampère's law obeys the last-named law also for the elements.

Gauss's next advance was concerned with the magnitude of the electrodynamic forces. He succeeded in showing that a so-called electrodynamic potential can be specified, the partial derivatives of which, with respect to the parameters that determine the position of the moving current conductor, yield the electrodynamic forces which tend to cause these parameters to increase. This is the first part of 'Neumann's law of potential'. Gauss then made use of the fact observed by Lenz, that the induced current has a direction such that the electrodynamic forces resist the motion, so that in consequence positive work is performed during this motion. On this basis he derived from the law of the electrodynamic forces the law of the phenomena of induction, which latter are therefore likewise closely linked with the expression for the 'Neumann-potential.' This is precisely the same train of thought which was followed later also by Franz Neumann and finally by Helmholtz in his famous paper, "Über die Erhaltung der Kraft" (on the conservation of force), a train of thought that can be formulated in modern terms by the statement that the phenomena of induction can be deduced from the law of electromagnetism and the energy principle, or that the laws of electromagnetism and of induction together are compatible with the energy principle. Finally, we again meet with the same train of thought, for example, in the derivation of Poynting's theorem from Maxwell's equations. The discovery of these relations may well be designated the pinnacle of Gauss's achievements in physics.

Nevertheless, Gauss was not content with what he had already achieved. In those days the problem was not regarded as having been solved until it was possible to trace it back to the position and motion of electrical charges, that is, the general fundamental law was sought for in a generalisation of Coulomb's law. This process of thought had its ultimate foundation in the unique authority of Newton's law of gravitation, with which Coulomb's laws agreed in their form. The true key to Nature was descried in generalisations of these laws. These endeavours culminated in the well-known law of Weber (1845–47). Gauss had also attempted to formulate such fundamental laws (1835), and one of them, designated Gauss's fundamental law, is examined in detail, for example, in Maxwell's "Treatise". Gauss himself had already proved that the basal law represents correctly the electromagnetic phenomena; on the other hand, Maxwell showed that it fails with the phenomena of induction. We are probably right in assuming that Gauss also recognised this deficiency, for he did not publish this law. In fact, practically all of the physical discoveries mentioned here first became known when his unpublished papers became available.

Whereas these developments of Gauss's ideas stand in diametrical contrast to Faraday's ideas of a field action, in later years Gauss nevertheless drew nearer to Faraday's view. This is clear from a celebrated letter written to Wilhelm Weber in the year 1845. In this Gauss states that the generalisations of Coulomb's law had not satisfied him, because they assumed an instantaneous ("instantanen") propagation, whereas *his* real aim had been the derivation of the forces from an action which is not instantaneous, but propagated in time in a similar manner to light. (In his letter to Weber, Gauss refers to a "nicht instantanen, sondern auf ähnliche Weise wie beim Licht in der Zeit sich fortpflanzenden Wirkung.") He frankly asserts that, in view of the fact that he did not succeed in arriving at the solution of this problem, he could see no justification for publishing anything about these electrodynamic investigations. We see here how closely Gauss's conceptions approach those of Faraday, and it is perhaps not entirely chance that Gauss's pupil, Bernhard Riemann, was the first to attempt, in 1858, to replace Poisson's equation for the potential $\Delta\phi = -4\pi\rho$, by the equation, $\frac{1}{c^2}\cdot\frac{\partial^2\phi}{\partial t^2} - \Delta\phi = 4\pi\rho$, which would result in propagation of the potential with the velocity of light, c.

It is clear from the above considerations that the discoveries of the years 1820–31, and especially the discoveries of Ørsted and Faraday, supplied Gauss with the material for his investigations. He was not really a physicist in the sense of searching for new phenomena, but rather always a mathematician who attempted to formulate in exact mathematical terms the experimental results obtained by others. Thus the brilliant achievements of Gauss would have been impossible had it not been for Faraday's discovery of induction, the centenary of which we are celebrating this year.

May then this brief outline also redound to the glory of Faraday, to whom in very truth those words apply which are to be found on Newton's grave:

> "Congratulentur sibi Mortales,
> tale tantumque exstitisse decus generis humani."

---

[1] Only since 1929 has it been possible to review with certainty Gauss's accomplishments in the field of electrodynamics in their entirety. Readers who are interested in this matter may refer to my essay "Gauss' physikalische Arbeiten" (Julius Springer, 1929), which has also appeared in "Gauss' Werken", vol xi, 2

[2] "Morgens 7 Uhr vor dem Aufstehen" (At 7 o'clock in the morning, before rising), these are the words of Gauss's entry.

[3] It was not known until recently that Gauss was also the discoverer of the law of Grassmann. We must ascribe blame for this to a slip on the part of Gauss, which has been overlooked hitherto, and which rendered his formula unintelligible.

Italian Physicists and Faraday's Researches.

By Prof. Vito Volterra, For.Mem.R.S., Royal University, Rome.*

THE discoveries made by Faraday were so numerous and important that they brought about a new and immense development of physics, and inspired the most varied and remarkable practical applications. The concepts that guided him in his famous experiments modified our ideas of natural phenomena so profoundly that a new epoch in the history of natural philosophy begins with him.

There has been no worker in the field of physics in recent years whose labours have not been more or less directly linked up with Faraday's. For that reason, if one wanted to mention all those who can claim to have continued his work or who have taken advantage of its results, one would have to name every physicist of modern times. This is as true of Italy as of other countries. This is not the place to embark upon the history of physics in Italy during the last hundred years, and I propose to deal rather with those researches which were most directly inspired by Faraday's, particularly at the time when the latter were first made known and had their greatest success and most important applications.

I will therefore go back to the autumn of 1831, when Faraday's attempts to obtain electric currents by means of the action of magnets were finally crowned with success. The results were not communicated to the Royal Society in London until November of that year, but the publication of the memoir was delayed, and the French translation only appeared in May 1832, in the *Annales de Chimie et de Physique*. In order to make up for this delay, Faraday wrote a very concise letter on the subject to Hachette of Paris, who brought it before the Academy of Sciences in December 1831.

Nobili, of the Museum at Florence, a physicist of unusual ability, who was already well known for his astatic galvanometer and his thermoelectrical studies, among other things, heard of the discovery from Amici, who had read of it in the *Temps*. Realising at once its vast importance, he set about repeating Faraday's experiments with the assistance of another Florentine physicist, Antinori. Their first memoir appeared in January 1832, and is explicitly so dated, but it was published in the *Antologia* for November 1831, which was very late in appearing.[1] Further papers came out in subsequent numbers of the same journal.

The two Florentine physicists obtained induced currents by approaching a closed circuit to the pole of a magnet, by breaking a circuit formed by a horseshoe magnet and its keeper, by reversing the current in a helical circuit arranged parallel to a dip needle, and by introducing a core of soft iron into a helix forming part of a closed circuit.

These experiments would not have provoked a controversy (one of the few in which Faraday engaged) but for the observations that accompanied them, particularly with reference to Arago's magnetism of rotation and the induction spark. The delay in receiving the authentic text of Faraday's memoir, and the misinterpretation of his letter to Hachette, contributed to the creation of the misunderstandings which gave rise, as Naccari points out, to the controversy mentioned above.[2]

The study of induction was carried on in Italy, in particular by Matteucci, who gave his attention to the distribution of the currents in Arago's rotating disc and to the magnetism of rotation, and published in 1854 his "Cours spécial sur l'induction, le magnétisme de rotation . . .", which gave an extensive account of as much as was then known with regard to the phenomena of electromagnetic induction.[3]

There is, however, a work of much greater philosophical and experimental importance, the memory of which I should like to revive. In 1852, Felici, who was at that time Matteucci's assistant and afterwards succeeded him in the chair of physics in the University of Pisa, began the publication of three memoirs entitled "Sulla teoria matematica dell' induzione elettro-dinamica".[4]

F. Neumann had already given his famous formula in his two works of 1845–47, and Weber's had appeared in 1846. Felici left the paths which these two scientific workers had trodden, and set himself to obtain the formulæ expressing the laws of electromagnetic induction by going step by step along the road of pure experiment by which, a quarter of a century earlier, Ampère had arrived at the mathematical expression of the mechanical force which two elements of current exert on one another. Like Ampère, Felici rested his case in his first memoir solely on experiments involving balance methods. By an ingenious arrangement, he intensified the effect of the induction, repeating the making and breaking of the current, and integrated with his galvanometer the intensities of the repeated induced currents of the same direction. He thereby obtained a formula which gives the electromotive force corresponding to the action of elements of current—a formula containing a term which vanishes when the electromotive force round closed circuits is integrated. Thus Felici's formula, besides telling us something more, supplies experimental proof of that obtained by Neumann by means of special hypotheses in extension of Lenz's law.

---

* Translated by T. Mark.

In his subsequent memoirs, Felici studied induced currents, not only in filiform circuits, but also in conductors of more than one dimension, thus linking up with Matteucci's experimental researches set forth in the " Cours spécial " referred to above.

Ottaviano Fabrizio Mossotti, one of the most eminent Italians of last century, was teaching in Pisa at the time when Matteucci and Felici were working there. Born at Novara (Piedmont) in 1791, he obtained his doctorate at Pavia, studied there with Brunacci, and also heard Volta. Political persecution forced him to leave Italy, and he went to France and to England, where he was received with great esteem and had many friends. He was first invited to Argentina, then went as a teacher to Corfu while it was under English protection, and finally to Pisa in Tuscany, where he founded an astronomical and physico-mathematical school which has been of great importance in the recent history of science in Italy.

Among Mossotti's numerous and beautiful researches, the one that now stands out as the most important, and to which he chiefly owes his fame, is the theory of dielectrics. Faraday devoted the eleventh and twelfth series of his " Experimental Researches on Electricity " to the study of the action of dielectrics in the phenomena of electrostatic induction. This effect had already engaged the attention of Avagadro [5] for many years, but Faraday's famous and decisive experiments established its nature and led to the theory of the polarisation of dielectrics.

Mossotti's great merit is that he showed the relation of the theory of electrical induction in dielectrics to the theory of magnetic induction. Now, Poisson had supplied the mathematical theory of magnetic induction ; so one had only to read in the language of *electricity* what Poisson had arrived at in terms of *magnetism* in order to obtain a mathematical theory of dielectrics based on the concepts of Faraday. Indeed, part of Mossotti's memoir of 1846 [6] is, as the author himself points out, nothing but a reproduction of Poisson's. The remarkable and elegant conclusions that Mossotti drew from it, and the interesting applications that have been made of it by others, such as Clausius, for example, who applied it to oscillating discharges, make Mossotti's work particularly valuable.

This brings us to Mossotti's own concepts with regard to the constitution of matter, a subject to which he frequently returned, as in a memoir dedicated to Plana [7] in the foreword to his Corfu lectures,[8] and on other occasions. Faraday, in the nineteenth series of his "Experimental Researches", shows his approval of these ideas of Mossotti's, which corresponded in a measure to his own. They deserve to be re-read to-day, to be pondered over and compared with the most modern theories, for, although the fact that they were thought out before the development of thermodynamics renders them remote from the present conception of many phenomena, they nevertheless may contain the germ of many fertile ideas.

The study of dielectrics, which had been fully investigated by means of Mossotti's mathematical analysis, did not come to a halt in Italy, but was continued in various works, among which I may mention those of Belli, Matteucci, and Felici on dielectric constants, and Felici's own investigations on the viscosity of dielectrics. Theoretical and practical researches of this kind have been continued down to our own days in the writings of Italian physicists and electro-technicians.

Mossotti's analysis is an example of the adaptability of Faraday's ideas to treatment in mathematical form. It is not the only example, nor is it the most famous, and indeed it is well known that Maxwell succeeded in translating Faraday's concepts into the equations of the electromagnetic field, and discovered in them the germ of the electromagnetic theory of light.

Faraday did not possess the technique of the analytical mathematician, but he could express accurately in words all that is told us by formulæ. The same thing may be said of Volta. If I wished to draw a parallel, after the manner of Plutarch, between these two heroes of science, I should have to bring out this similarity between the minds of the English physicist and the Italian, which were also so much alike in other ways. Both had mathematical minds in the truest sense, for analytical symbols and devices are not the substance of mathematics but only its outward aspect.

The problem of the electric motor, and its converse, that of generating the electric currents first obtained with Volta's pile, and then, thanks to Faraday's principle of induction, by a method capable of practical application on a large scale, were certainly ' in the air ' when a very ingenious solution was supplied in 1860 by Antonio Pacinotti, who constructed his celebrated ring armature in the Technological Physics Laboratory of the University of Pisa. It was not until 1864 that the inventor set down in writing a description of his apparatus, which he modestly styled "una machinetta elettromagnetica" (a small electromagnetic machine), and he published it in 1865 in the *Nuovo Cimento*.[9]

I do not think it worth while to give this description here, for it appears in most elementary treatises on physics and electro-technics. The brilliant solution of the problem proved to be adapted to the most extensive and important industrial applications, which the inventor himself had at once foreseen, and the machine became one of the most useful and most widely employed in the world. There is no need to repeat the well-known story of its rapid dissemination and the controversies, now concluded, to which it gave rise.

As we have already said, the researches connected with Maxwell's theories cannot be dissociated from the memory of Faraday, to such an extent are the theories themselves derived from his experiments and concepts. The pressure of light, which Maxwell arrived at as a consequence of the electromagnetic theory, was demonstrated by Bartoli, by a new and original method, described in a memoir published in 1876, which was practically devoted to the study of the radiometer.[10] Bartoli imagines four concentric spherical enclosures: the outermost and the innermost are perfectly black; the two in between are perfect reflectors. By means of a cycle, which may be repeated as often as desired, he makes heat pass from the outermost enclosure, which may be assumed to be the coldest, to the innermost, which may be assumed to be the warmest. In accordance with the second law of thermodynamics, before the cycle can be completed a certain amount of work must be changed into heat, and then, by virtue of the radiation of the black body on the inside, a pressure is exerted on the adjacent enclosure. From this follows, as a consequence, the pressure of light.

This is the most celebrated of Bartoli's numerous investigations, and it is undoubtedly with this that his name is always associated. The curious thing is, however, that Bartoli, who died in June 1896, before the pressure of light had been experimentally verified, was doubtful of its reality and strove to interpret his reasonings in various other ways; but he always kept his doubts to himself while he lived, and they were only revealed later on.

We must also mention Bartoli's researches in electrolysis, and in particular his investigations into the possibility of decomposing water even with the weakest electromotive forces.[11] They are allied to Faraday's studies in his fifth and following series of "Experimental Researches".

The prime characteristic of Faraday's thought lies in his transference of the seat of electromagnetic phenomena into the dielectric, where he perceived and followed the movement and the changes of the lines of force which were the embodiment of the conception he had used to explain electrodynamic action.

One of the most luminous and inspiring expositions of Faraday's conceptions, and of the manner in which they were developed by Maxwell and Hertz, was the address on the electrical transmission of energy delivered by Galileo Ferraris to the Academy of the Lincei in June 1894.[12] But an address of this kind would only be remembered as a happy popularisation of the concepts of the localisation and flux of energy, at that time novel to the public at large, if it did not serve to show us a good deal more, namely, the quality of Ferraris's intimate insight into the nature of electrical phenomena, which had been the point of departure for his discovery, nine years earlier, of the rotary magnetic field. Indeed, it was seeing 'in his mind's eye' the electrical vibrations completing themselves, not within the confines of the conductors, but in the common medium external to them, and thus persuading himself of the possibility of superimposing two alternating electrical currents at right angles to one another—a vision that came to him like a flash as he was taking a lonely walk one night through the streets of Turin—that led Ferraris to the discovery to which he chiefly owes his fame.[13] This brilliant achievement had been preceded by lengthy and searching studies of transformers, of which Ferraris provided a complete theory which led him to establish the well-known law of phase-displacement and to work out the power of a transformer. This served to dissipate the mistaken views then prevalent regarding the output of a transformer, and to show the full importance, in its industrial applications, of this fundamental piece of apparatus, the direct offspring of the principle of induction, occupying in electro-technics the place of the lever in mechanics.[14] The transmission of energy over a distance by the use of alternating currents, from which all our industries have received so great an impetus, was the practical outcome of these studies.

The history of the evolution of Faraday's ideas, which led to Maxwell's mathematical theory, then to the experiments of Hertz, would not be complete without some reference to wireless telegraphy, in which the memorable cycle reaches its astounding close. In Italy, Righi, among others, repeated and successfully extended Hertz's experiments, following out in every particular the analogies between the phenomena of optics and those of the electromagnetic waves.[15] Then Marconi, with amazing perseverance, availing himself of the most ingenious and varied methods, succeeded in carrying out actual transmission over a distance by means of electromagnetic waves. The rapid progress of radiotelegraphy and radio-telephony is going on every day before our eyes, and is being followed with interest and wonder throughout the world.

I cannot enlarge on numerous other questions, interesting though they are—electrolysis and electrophysiology, for example—or recall Matteucci's studies [16] and his correspondence with Faraday,[17] nor must I go back to the chemical theory of the Voltaic pile, which Faraday preferred to the contact theory, thus associating himself with the ideas first put forward by Fabbroni.[18] It is impossible for me to say anything on the question debated by Faraday, whether electricity, however generated, is always the same, follows the same laws, and produces the same effects; Volta himself considered this problem, and has been the subject of recent studies by living writers. I will only mention the observations communicated by Father Bancalari in 1847,[19] and the subsequent memoir by Zantedeschi on the magnetism of flames,[20] which attracted Faraday's attention to the magnetism and diamagnetism of gases.

Let me close with a reference to magneto-optics, which takes its rise from one of Faraday's most famous discoveries, that of rotatory magnetic polarisation. Righi gave the dynamic explanation of the phenomenon, which later researches have associated with Zeeman's great discovery. Righi himself took advantage of the property of a sodium flame traversed in the direction of the field by a beam from two crossed Nicols, which permits of the observation, by simple means, of Zeeman's converse phenomenon.[21] It is very curious that this experiment should have been carried out with apparatus analogous to that devised by Faraday, who, however, failed to obtain the result, an occurrence extremely infrequent in the course of this great observer's researches.

We are to-day recalling and commemorating the work of Faraday, as we did that of Volta and of Ampère a few years ago. These three great men of science, belonging to different countries, lived their lives remote and apart from each other, but their minds worked together in harmony for the progress of natural philosophy and the discovery of new and marvellous devices of use to human society. The influence which each of them exercised beyond the confines of his native land availed to direct towards similar ends minds very diverse in their racial origin, which acquired fresh virtues by taking part in the common effort.

The aim of my brief essay has been to throw light on the influence which Faraday's work had in Italy. From the philosophical point of view, this influence was enormous, and, as we have seen above, when the discoveries of the English physicist penetrated into Italy, they gave rise to new and original discoveries there, of singular importance even from the point of view of their practical applications, which awakened the enthusiasm not only of men of science but also of the whole of the civilised world for which they have provided such benefits and advantages. The feelings of admiration and gratitude cherished in Italy towards the great British thinker and experimenter are widespread and profound.

Faraday and French Physicists.*

By Prof. Pierre Brunet, Centre international de Synthèse, Paris.

Even if it is one of the essential tasks of the historian of science to find exactly what work was done by certain savants, he should still aim at showing the continuity of effort and research—if not of discoveries—by determining the place of the piece of work in question, its antecedents and consequences, what discussion was centred on it, and the depth and rapidity of its penetration into scientific thought. The necessity for consideration of environment would appear to be less if the savant belongs to a fairly recent period, since the speed with which discoveries become generally known has increased steadily through the centuries with the development of what may be called the internationalisation of science.

In the case of Faraday we are naturally led to inquire into the relation between his work, that of his own countrymen, and that of foreign savants. Even when we limit our study to that of the French physicists, under the last head, we are still left with a large field, and are compelled to restrict it further for the purposes of the present article. Without attempting, then, to give an exhaustive treatment, and passing over bibliographic matter—this would involve a very large number of references, and we should have to refer in particular repeatedly to thirty or forty numbers of the *Comptes rendus de l'Académie des Sciences* and as many volumes of the *Annales de chimie et de physique*, without counting a certain number of issues of the *Bibliothèque universelle* of Geneva and of *Poggendorffs Annalen*, where the French savants also published articles—we should like to point out specially, in a general way, what were the main lines of thought.

In the report on the founding of a prize for electricity presented by Biot to the Institut on July 1, 1802, which is signed by Laplace, Halle, Coulomb, and Hauy, an epitome of the history of electricity makes it appear that a second phase had started with Volta. The work of the Italian physicist had indeed not been long in making its effects felt in France, and had been taken up with some enthusiasm and had soon raised exaggerated hopes. Dumas alluded to this in his *Éloge de Faraday* when he referred his hearers "aux souvenirs d'une époque où les professeurs de physique exposaient à leur auditoire étonné la théorie mystérieuse de la pile voltaïque ; le simple contact de deux métaux, qui ne perdaient ni ne gagnaient rien, disaient-ils, faisait néanmoins sortir de cet appareil magique des effluves capables de rivaliser avec l'éclat du soleil . . . ."[1]

The first to question seriously this 'mystical theory' of contact was Becquerel, in France, who communicated a paper to the Academy of Sciences on May 19, 1823, dealing with his researches on thermoelectric phenomena and the electric effects of chemical reactions. His memoir of July 7, 1823, on the electric effects which develop during various chemical reactions, is of capital importance ; it was followed on Sept. 22, 1823, by another paper in which he described a method for measuring the intensity of a chemical reaction by the resulting electrical effects. He described other experiments in November 1823. Finally, he completed his work on April 12, May 31, July 5, and Oct. 3, 1824, by giving an account of a theory of the distribution of electricity in the voltaic cell, and by a discussion of various points arising out of his previous work. This established the general laws of the production of electricity by chemical action. Becquerel was able to construct a cell giving a steady current in 1829, after a first attempt in 1826.

Electricity produced chemically was studied after Becquerel by Pouillet, who presented two very important papers to the Academy of Sciences in 1825 (he also gave the results of his researches on the electricity of elastic fluids and on the origin of atmospheric electricity), and continued this work until 1828.

Whilst the work started by Volta was being developed in France on these lines, the experiment of the Danish physicist, Ørsted (July 21, 1820) was opening up the way for Ampère's and Arago's discoveries in electromagnetism. It would be interesting to give some details of Ampère's experiments. However, to keep strictly within the plan of this study, we shall merely recall the main features of the work, during the course of which the author established the basis of electromagnetism in a few months. The paper presented to the Academy of Sciences on September 18, 1820, is particularly worthy of attention, not only as the first, but also because the views expressed there contain the germ, so to speak, of all the subsequent work. We find established here the existence of an effective electrodynamic force in all parts of the conducting wire as well as in the cell, the notion of the direction of a current, the means of recognising this direction, and finally the general law determining the sense in which the current deviates the needle. Further, Ampère gave there a description of some instruments which he had designed, and elaborated some remarks tending towards an explanation of the properties of magnets. The papers of Sept. 25 and Oct. 9 were devoted to the study of the action of one current on another. During this time, Arago, following up some experiments with Gay-Lussac, had demonstrated the magnetisation of a needle placed in a spiral of wire carrying a current and the attraction of a conductor for iron filings;[2] and announced on Nov. 10, 1820, in the *Moniteur universel* that he had magnetised iron needles by electric sparks.

---

* Translated by Dr. K. G. Emeléus.

Whilst Biot was communicating results of experiments he had undertaken with Savart to the Academy at the meeting on Oct. 30, and formulated the law which goes by their names, Ampère was continuing to publish his work, his concluding communications being made on Oct. 30, Nov. 6, and Dec. 4 (1820), and on Jan. 8 and 9 (1821).

At the end of this year (1821) Faraday's work and Ampère's work became closely connected for the first time. It was indeed Ampère's experiments which had given Faraday the idea of making a current element rotate by means of a magnet (we may note that Wollaston had already had this idea) and had made him try the converse experiment. The result of this double experiment in turn led Ampère to extend it, at the same time making his theory of magnetism more exact, and also to remedy its partial failure by improving certain faulty arrangements.

Ampère established the production of electric currents by induction so early as 1822. "Il s'établit", we read in "Recueil d'observations électro-dynamiques" (p. 321), "dans un conducteur mobile formant une circonférence complètement fermée un courant électrique par l'influence de celui qu'on produit dans un conducteur fixe, circulaire et redoublé, placé très près du conducteur mobile, mais sans communication avec lui." About this time Ampère also arrived at the fundamental law of electrodynamics by studying the phenomena of rotation of current elements by means of two circuits.

Whilst other physicists entered the field of electromagnetism, Ampère and Arago persisted in their research, and in 1824 the latter, following up an experiment of Gambey (1824), made the new discovery of magnetisation by rotation. He first ascertained that a magnetised needle returns much more rapidly to its position of rest when oscillating if it is put over a non-magnetic metallic disc, and then showed that the needle was deviated when a non-magnetic metallic disc was rotated above or below it. Arago went still farther and found the direction of the resultant action of the disc on the needle (1826). Before he had taken his analysis of the phenomenon even thus far, however, Prévost and Colladon, working in conjunction with Ampère, recorded (1825) the damping action of a fixed intercalated disc, and in 1826 Ampère showed in collaboration with Colladon that a spiral of wire passing a current was acted upon by the disc like a magnet. Physicists were very puzzled, nevertheless, when it came to explaining these phenomena. It was at first thought that it was a question of induced magnetism, all bodies being supposed to be capable of showing magnetic properties (an idea put forward by Coulomb in 1812), but this suggestion was soon discredited by Arago himself (1826). We can see from this how very far he had progressed towards the idea of induced currents, and how in quite a different way from Ampère, but just as directly, he had reached, so to speak, the frontier of the discovery reserved for Faraday.

There is no doubt that the ground had been prepared for Faraday's work in this way in all directions by the French physicists; and when their contemporaries mentally compared Arago and Ampère with Faraday they let themselves be guided by a proper understanding of the connexion between Faraday and his French rivals. Dumas wrote in his *Éloge de Faraday* that "Quand l'électricité aura trouvé son Newton, on pourra dire que, si Ampère en fut le Kepler, Faraday en fut le Galilée". He then drew a parallel between "ces deux hommes, si divers par les dons de la nature, si rapprochés par le génie et par les travaux", "inséparables dans le tableau du mouvement scientifique dont l'électricité a été l'objet, comme dans le souvenir de ceux qui les ont vus à l'œuvre". We do not think it is correct to add that "ce que l'un a fait, l'autre aurait pu le faire", or to write, as Becquerel did, that "si Ampère eût cherché à vérifier par expérience quels étaient les effets produits par les courants électriques sur les corps à l'état neutre, ainsi qu'il l'avait annoncé, il aurait enlevé à Faraday l'honneur de la découverte de l'induction". Nothing is less certain and more fallacious than a retrospective prediction after an event has taken place. Scientific discoveries have their origin in spontaneous inspiration, which is not part of a logical development and outside the range of extrapolation. The historian of science has done enough when he has established connexions and priorities and his function ends there.

The effect of Faraday's discovery in France, when it was announced to the Academy of Sciences by Hachette on Dec. 17, 1831, can be readily imagined. Not only did his results support Ampère's ideas on the structure of magnets, and by making it possible to pass from magnetism to electricity bring out clearly the identity of the two sets of phenomena, but also the idea of induction seemed especially fruitful from the fact that the existence of induced currents explained satisfactorily what Arago had found about magnetisation and rotation. In fine, Faraday gave a new cohesion to discoveries which had remained, if not isolated, at least somewhat separate; he imparted some sort of unity to convergent ideas which were not obviously comparable, his work being at once synthetic and explanatory.

In another connexion, Faraday's researches on cells led him to reject completely contact action, by his insistence on the chemical origin of the electrical energy of the cell. His influence in France in this matter was a powerful contributory factor in the overthrow of the contact theory, which still persisted in spite of Becquerel's work. Seen from this angle, Faraday's rôle was to supply the necessary support to a piece of work which had not been completely accepted, and which received in this way the authority needed for it to become properly established.

After this, French physicists undoubtedly paid more and more attention to Faraday's researches, and looked to them both for suggestions and direction. For example, shortly after Faraday discovered self-induction, Masson was engaged in 1837 in finding the conditions under which currents could be produced by this means. He succeeded later in finding the relation between the tension of the currents and the sense of the induced currents. Moreover, following up a remark of Faraday's, he and Bréguet studied the conditions which determine the static effects which occur when currents are induced. Abria (1843) and Verdet tried especially to develop the results obtained outside of France by Henry (1839), but the induced currents of various orders studied by him constituted, nevertheless, a sort of extension of Faraday's discovery, and the two French physicists worked under the inspiration of the great English physicist. Still later, to quote only a few examples, it is perfectly certain that the experiments which Lallemand did between 1848 and 1851 on the mutual attraction and repulsion of induced currents, and Foucault's discovery of the heat developed by induction of currents (1855), are closely connected with ideas which originated with Faraday himself.

In sketching above the electrical research done in France prior to Faraday's work, we have ignored two small pieces of work which were too isolated to have any immediate effect. These were Le Baillif's observation of the repulsion of bismuth by a magnet, and Becquerel's observation (1827) of the repulsion of antimony under the same conditions. It was again left to Faraday to find the explanation by discovering diamagnetism, which groups these with other phenomena; even this mention of them, however, gives them rather undue prominence, since it can scarcely be maintained that Faraday's work was anticipated in France. On the other hand, he very soon had pupils, notably Ed. Becquerel, who first showed how to measure the attraction and repulsion of a magnet for different bodies in 1849, and perfected his method the following year and made it possible for Faraday to take up the problem again in the same way and push the solution much farther.

Finally, Faraday's letter to Dumas on Jan. 17, 1845, in which he announced the discovery of rotary magnetic polarisation, had an immediate effect in France. It was the origin of the work of Pouillet (1846), Ed. Becquerel (1846), and again of that of Verdet (1854). We cannot even make a brief study of these researches, and merely mention them to indicate the trend of later work, and the many directions in which the work of French physicists was orientated by Faraday. They were, moreover, not merely distant pupils; they found a living example in their teacher, who was to all intents and purposes a valuable collaborator, always ready to advise them, or to encourage them by some expert suggestion. Dumas tells us that "Foucault, dont les procédés avaient tant d'analogie avec ceux de Faraday dans l'art de consulter la nature, ne fut jamais plus heureux, peut-être, que dans les occasions où il l'avait pour témoin intime de ses admirables expériences". One can appreciate the prestige of the great English savant amongst his contemporaries, and his enthusiasm for scientific research, when one considers the admiration implicit in the following passage from Dumas, describing how Faraday allowed him to be present at one of his experiments: "Ses yeux pleins de feu, sa physionomie animée, témoignaient du sentiment passionné qu'il portait à la découverte de la vérité".

---

[1] It is interesting to notice that Biot himself spoke in his report with some wonder of electricity being put into motion 'by simple contact'.

[2] Arago having shown this experiment to Ampère, the two then collaborated in new work.

Faraday's Connexion with Switzerland and Swiss Industrial and Economic Development.

By Ch. Eug. Guye, Honorary Professor of Physics in the University of Geneva.*

IT was through being assistant to Sir Humphry Davy that Faraday came into contact with the Swiss savants, and most particularly, at Geneva, with Gaspard de la Rive, then professor of chemistry in the Academy of that town, and with his son Auguste de la Rive, the great physicist, well known for his treatise on theoretical and applied electricity, his theory of the Volta cell, and his discovery of electro gold-plating, etc.

Apart from his invention of the miners' safety lamp, which made his name so popular, Sir Humphry Davy discovered the electric arc, that extremely valuable aid to science and industry, which has made possible the attainment of very high temperatures in the electric furnace and has revolutionised both illumination and the metallurgical industry.

Switzerland is, however, indebted to Sir Humphry Davy not only for his discovery of the electric arc, which benefits its industry, but also for taking Faraday to Switzerland and introducing him to the savants of the country. Geneva is greatly honoured in having and caring religiously for the tomb of the illustrious English chemist in the ancient cemetery of the Plainpalais commune.[1]

We may perhaps recall the circumstances which took Faraday to Switzerland.[2]

Faraday had been filled with enthusiasm by the lectures which Sir Humphry Davy gave at the Royal Institution in 1812, and he sent his notes on the lectures to Davy. In the following year a vacancy occurred for the post of laboratory assistant, and Faraday was appointed to it by Davy, giving up the work in a bookseller's shop in which he had been engaged for several years. A little later, Davy discontinued his work as professor at the Royal Institution to travel through Europe with Lady Davy to study. Faraday accompanied him as his laboratory attendant. They took with them a small portable cabinet which allowed them to do some chemistry on the way. They went first to Paris, which they reached on Oct. 27, 1813, and where Davy presented various notes to the Academy. On Dec. 13, this body appointed him as one of its associate foreign members in the first class. Leaving Paris, Davy, still accompanied by Faraday, stopped at Montpellier, where he met the celebrated Geneva botanist, A. P. de Candolle. We see him in Italy in 1814, and finally, towards the middle of September in the same year, we find him at Geneva, where he remained until the beginning of winter. He finally proceeded to London in the spring of 1815 by way of Austria and Germany.

Thus it happened that by accompanying Sir Humphry Davy on his travels, Faraday had the opportunity of coming into contact with Swiss savants, and particularly with Gaspard and Auguste de la Rive, with whom he kept up a sustained correspondence afterwards, which is now deposited in the public University library of Geneva.[3]

These letters make it clear that Faraday and the Geneva savants were in communication for many years on scientific matters, exchanging opinions from time to time on each other's work. There is neither time nor space at present to go into this in detail, but we can perhaps return to it at some future date. There does, however, emerge from this intimate correspondence an impression of mutual confidence and of profound friendship. We may be permitted to quote in this connexion a letter which Faraday wrote, dated Oct. 16, 1852, when, having reached an age of some sixty years, he felt the first touches of age, although his exceptional activity might still make many a savant envious. A vein of modesty and sincerity brings out all the sympathetic greatness of this choice nature.

à Monsieur Auguste de la Rive,
PRESINGE
Geneva, Switzerland.

Royal Institution,
16 October 1852.

" My dear De la Rive,

From day to day and week to week I put off writing to you, just because I do not feel spirit enough; not that I am dull or low in mind, but I am as it were becoming torpid: a very natural consequence of that land of mental fogginess, which is the inevitable consequence of a gradually failing memory. I often wonder to think of the different causes (naturally) of different individuals, and how they are brought on their way to the end of this life. Some with minds that grow brighter and brighter but then physical powers fail; as in our friend Arago; of whom I have heard very lately by a nephew who saw him on the same day *in bed* and at *the Academy*: such is his indomitable spirit.—Others fail in mind first, whilst the body remains strong, others again fail in both together: and others fail partially in some faculty or portion of the mental powers, of the importance of which they were hardly conscious until it failed them. We may, in our course through life, distinguish numerous cases of these and other natures; and it is very interesting to observe the influence of the respective circumstances upon the characters of the parties and in what way these circumstances bear upon their happiness. It may seem very trite to say that *content* appears to me to be the great compensation for these various cases of natural change; and yet it is forced upon me, as a piece of knowledge that I have ever to call afresh to mind, both by my own spontaneous and unconsidered desires and by what I see in others. No remaining gifts though of the highest kind; no grateful remembrance of those which we have had, suffice to make us well and be content under the sense of the removal of the heart of these which we have been conscious of.

---

* Translated by Dr. K. G. Emeléus.

I wonder why I write all this to you: Believe me it is only because some expressions of yours at different times, make me esteem you as a thoughtful man and a true friend.—I often have to call such things to remembrance in the cause of my own self examination and I think they make me happier. Do not for a moment suppose that I am unhappy. I am occasionally dull in spirit but not unhappy; there is a hope which is an abundantly sufficient remedy for that, and as that hope does not depend on ourselves, I am bold enough to rejoice in that I may have it. . . ."

Now that we have recalled the circumstances which took Faraday to Switzerland, let us see what consequences his discoveries, in particular his discovery of electromagnetic induction, have had in the industrial development of our country.

It is no exaggeration to say that Faraday's discovery is, with that of Ampère, one of those which has contributed the most to our civilised life. Its influence on pure physical science has been admittedly fundamental. Without dwelling on the scientific consequences of this work, we may recall that the discovery of induction, taken up and developed by the illustrious English physicist Maxwell, has become the explanatory basis of the theory of light, and, more generally, of all electromagnetic wave phenomena, which embrace more and more the whole of physics.

It is, however, above all, in its numerous applications that the discovery of induction has been so marvellously fruitful; as we know, these applications have altered the very face of our civilised world.

This transformation has been particularly significant in Switzerland; applications of electricity have rapidly assumed a place of first-class importance in this country. The immense water power which Switzerland employs has in fact only become available through the possibility of transforming it into electric energy, which permits of carrying and distributing it through the whole country, including the most secluded valleys.

To attain these marvellous results, it has been necessary in the first instance to build generators, motors, and electric transformers, the operation of which is controlled fundamentally to a considerable extent by the laws of induction, the discovery of which is due to Faraday's great genius.

At the present moment, the power in use for the production of electric energy in Switzerland is more than a million kilo volt-amperes and the electric energy produced annually by the whole of these installations now reaches about four milliard kilowatt-hours (kw.h.).[4]

The establishment of immense hydraulic works was, however, necessary to capture this enormous energy; moreover, to obtain sufficient regularity in the utilisation of this water power (it is well known how a watercourse varies from one season to another), it has been necessary to accumulate immense reserves; to create by dams large artificial lakes, or to harness by more or less important pieces of work large lakes already in existence. The hydraulic energy accumulated in this way in these immense reservoirs exceeds four hundred million kw.h.

Amongst the artificial lakes made to provide the necessary reserve of energy, we may mention specially Lake Barberine (Valais), with a capacity of nearly thirty-five million cubic metres, and Lake Dixence (Valais), now in active course of construction and with a capacity of fifty million cubic metres.

At the same time, for topographical reasons, Swiss industries have been called upon to make use of considerable heads of water. The installation at Fully (Valais) employs a head of 1650 metres, necessitating conduits and turbines working at pressures of about 165 atmospheres. Even this record will shortly be beaten by the Dixense installation, which will utilise a head of 1750 metres.

All this hydraulic energy is transformed into electric energy in large installations by means of generators and sets of transformers; not only is it used to light towns and even the most remote villages in the high mountains, but also industry in all its forms absorbs a considerable proportion. Mechanical and electrochemical and electrometallurgical industries have grown up rapidly through the marvellous adaptability of the 'electric fairy' for distribution. In the first rank of the Swiss electrochemical industries one finds the Aluminium Company, with large factories at Neuhausen, Chippis, etc., the manufacture of ferrosilicon, and that of calcium carbide, finally used to a large extent for the manufacture of nitrogenous manures (cyanamide). Finally, the whole network of the Swiss railways has been completely electrified quite recently, and this change represents an annual consumption of about a half-milliard kw.h. Quite apart from the many advantages of electric traction, notably from the point of view of multiplicity of trains, the rapidity with which they can start from rest, the absence of smoke, etc., this electrification is a very considerable economy for Switzerland. It obviates the necessity for importing a quantity of coal worth some tens of millions of Swiss francs annually.

Such is a very brief account of the use of our natural resources in Switzerland, which has been made possible in the first instance through Faraday's fortunate discovery. It will be readily understood why the country which has had the privilege of giving birth to a genius whose work has been so astoundingly productive should have decided to honour his memory, and to celebrate the anniversary of one of the discoveries the consequences and repercussion of which have played so important a part in the whole of our civilisation.

---

[1] Sir Humphry Davy died at Geneva on May 29, 1829. He was buried on June 1 in the Protestant Cemetery at Plainpalais; the Conseil d'État granted a concession for 99 years, which was renewed a few years ago at the instance of the Faculty of Science of the University. In gratitude, Sir Humphry Davy's widow left to the Academy a sum to found a prize for the encouragement of scientific research.

[2] We take these details from an account of Sir Humphry Davy by the late Prof. Ph. A. Guye, of the University of Geneva.

[3] This correspondence contains about ten letters to Gaspard de la Rive (between 1818 and 1832) and about twenty-five letters to Auguste de la Rive (between 1840 and 1861).

[4] A kilowatt-hour corresponds to the energy developed by a machine of 1·36 horse power in an hour.

Faraday and Austria.*

By Prof. Karl Przibram, Institut für Radiumforschung, Vienna.

IN the autumn of the year 1814, towards the end of the Napoleonic drama, a travelling coach wended its way southwards over the picturesque mountain roads of the Austrian Tyrol. Its three occupants were the celebrated Sir Humphry Davy, his haughty wife, and a modest young man who played the part of a scientific assistant, and also, but with suppressed reluctance, that of valet. Waterfalls thundered down into the valleys, and the eyes of the young man followed them in wonderment. What were his thoughts? Deeply religious by nature and upbringing, was he simply admiring the works of the Almighty, or had he a glimmering presentiment of the possibility of harnessing these vast sources of energy for the benefit of mankind, to the realisation of which his later discoveries were to supply the key?

Young Faraday passed through the Austrian Tyrol twice during that memorable tour; but the influence which he exerted by his later discoveries, not only on Austria but also on the whole world, is in no way to be assessed by these fleeting visits. Is not water power an important asset of our sorely stricken country, and its present and future utilisation directly due to that flutter of a magnetic needle by which the first induction current revealed itself in Faraday's laboratory a century ago? We may recall to memory here two Austrians who though very different in station and in temperament, have both contributed to these extensive developments: first, the brilliant engineer and author, J. Popper-Lynkeus, who, far in advance of his time, upheld the possibility and necessity of electrical power transmission, in a thesis presented to the Vienna Academy of Sciences in the year 1862; and secondly, the university mechanician, Kravogel, of Innsbruck, who anticipated Gramme's ring in an electro-motor of his own construction.

Just as Faraday's discoveries opened up new avenues in engineering, so also, as a result of his novel ideas, translated into the language of mathematics by his great fellow-countryman, J. Clerk Maxwell, was physics confronted by new problems, in the solution of which Austria played no mean part. From amongst the four first magnitude stars in the constellation of Austrian physics—Doppler, Loschmidt, Stefan, and Boltzmann—the last two at least can be brought into direct relation with Faraday; Stefan by virtue of his researches on electrodynamic and diamagnetic induction, and Boltzmann as one of the first and most ardent protagonists, on the Continent, of the ideas of Faraday and Maxwell. Boltzmann's famous experimental investigations on the dielectric constant of gases and of sulphur can be regarded as a direct continuation of Faraday's pioneer work. We are moved as by a breath of Faraday's characteristic homeliness and devotion to his work when we hear of young Boltzmann waiting for hours for admittance to a classical performance in the Vienna Burgtheater, wedged in a crowd of art enthusiasts, and meanwhile, much to the displeasure of those around him, unremittingly polishing the sulphur spheres which he requires for his experiments.

Faraday's experiments on the liquefaction of

* Translated by Dr. R. W. Lawson.

gases were continued in Austria by Natterer, who constructed the first reliable machine for liquefying carbon dioxide; and Boltzmann's successor, Fritz Hasenöhrl, to some extent united the two last-named fields of Faraday's researches, dielectrics and the liquefaction of gases, by determining the dielectric constant of liquid air. Hasenöhrl fell in the War, in the defence of those selfsame Tyrolese mountains upon which Faraday's gaze may have rested little more than a hundred years earlier.

In view of the far-reaching influence of Faraday on contemporary physics, the selection of Austrian physicists referred to in this note is necessarily somewhat arbitrary. We might well also have drawn upon names such as E. Mach, V. v. Lang, L. Pfaundler, E. Lecher, and Franz Exner.

May the spirit of Faraday continue to dwell amongst us. It would be a sad prospect for science were those two complementary characteristics of Faraday's genius to depart from us—creative imagination and unconditional devotion to experiment.

The Faraday Festival.

By Prof. Bohuslav Brauner, Prague.

THE whole scientific world will join in celebrating Faraday's discovery of electromagnetic induction, and it will certainly not be passed over in Bohemia. I may be excused if I begin with myself. In our middle school (gymnasium) we had a most excellent teacher of physics, Prof. Pokorný. In his clear and beautiful lectures, which would have served as a model to those given at a university, he taught us in 1870 the principal discoveries in the domain of electricity. He spoke of Galvani, Volta, Carlyle and Nicholson, Ørsted, Ampère, and others, but before all he praised the discoveries of Faraday.

Pokorný accompanied his lectures by the most delicate experiments. We became so enthusiastic about the matter that we constructed many of his pieces of apparatus at home. I myself constructed first a Daniell cell, but for want of the necessary means the porous diaphragm was made of paper cardboard coated on both sides with plaster of Paris. A series of such elements gave a distinct spark between carbon poles. Further, I constructed a Neff's hammer, an electric alarm bell, an induction coil with condensers and a regulator, an electric telegraph for reaching a distance of a mile, an electric contact-thermometer showing the temperature at a distance and ringing the alarm bell to avoid an explosion—such as that which occurred in the dynamite works near Prague—and last of all an electric 'waker-up', ringing an alarm-watch. They were novelties in 1870, sixty-one years ago. It must be remembered that the art of 'electrotechnics' was founded only eleven years later, namely, in 1881, at which time the new electric units were established, the one mostly used up to that time having been the B.A. unit. Fifty years of NATURE, with which I became acquainted in 1880, has kept me well informed of further developments of electrical science.

Not only apparatus made by enthusiastic students, but also more serious investigations were made by some of our countrymen. Prof. František Petřina, a Bohemian, born in Semily in 1799, from the year 1844 ordinary professor of physics in the University of Prague, has done research work in galvanism, especially in telegraphy, as is seen from his many publications in *Poggendorfs Annalen* and those of the Vienna Academy of Sciences and so on. While teaching in Linz (1837–44) he constructed a simple instrument for 'faradisation': one magnet wound with insulated wire standing and another magnet on the top which could be turned round, so that the poles were changing. I saw the original model and also 'Petřina's spiral' largely used.

In the Bohemian University the theory of Faraday's discoveries was analysed by Prof. Koláček, professor of theoretical physics, but his work was rather to follow up that of Maxwell.

Prof. František Záček, physicist of the Bohemian University, has given me information upon the experimental significance of Faraday's discovery of electromagnetic induction: without Faraday's work, many aspects of electricity and the whole of electrotechnics could not be thought of. But also from the purely scientific point of view the value of this discovery is enormous, for it is a step showing a further connexion between electrical and magnetic phenomena, following on from Ørsted's discovery of the magnetic action of the electric current.

A further important discovery of Faraday is that of the chemical actions of the electric current and of the laws which it obeys. Besides the experimental importance of this work, due weight should be given to the theoretical side in connexion with our present views on the composition of matter and the atomic structure of electricity.

For the further development of electrical theory, Faraday's views on the relation of electric and magnetic phenomena, on the spreading out of the electric and magnetic forces through the dielectric, on the rôle of the same, on the tubes of force and so on, are highly important. In this respect Faraday may be regarded as the father of modern electrical theory, and he is the creator of the *Nahewirkungstheorie*. Faraday's views were further developed by Maxwell, and we find the fertile consequences not only in the purely scientific field (the electromagnetic theory of light), but also in the practical field (electromagnetic waves and radiotechnics). In this connexion, Prof. Žáček would like to direct attention to the fact that Faraday had a presentiment of the close connexion between electrical and optical phenomena, in pursuit of which he discovered the rotation of the plane of polarisation in the magnetic field.

Faraday's Researches and the United States.

By Prof. Willis R. Whitney,
Director of Research, General Electric Company, Schenectady, New York.

THE spirit and method of Faraday are as worthy of study as the results that flowed from them. Almost anyone could rehearse his cardinal contributions to present-day understanding of magnetic and electric fields, and could cite his electrochemical researches and his studies of magneto-optic and diamagnetic phenomena. No one ever before covered so wide a field of pure research, or discovered and disclosed such a grand territory of expanding and continuing usefulness. No one ever tapped so many sources from which living water flowed. But for anyone, however closely connected with that particular field of pioneering, to attempt to enlarge upon Faraday's work, seems to be lifting one's self by mere words into a position where the light of Faraday's character warms the writer without of necessity illuminating the rest of the world.

In his writings, Faraday touched the spiritual side of life lightly but revealingly when he said, "Yet even in earthly matters I believe that the visible things of Him from the creation of the world are clearly seen, being understood by the things that are made, even His eternal power of Godhead: and I have never seen anything incompatible between those things of man which can be known by the spirit of man which is within him and those higher things concerning his future, which he cannot know by that spirit."

The establishment of publicly supported institutions for the advancement of physical knowledge which was marked by the Royal societies and academies about 1700, looks, at this distance, like an attempted answer to Bacon. Nearly two hundred years before Faraday, Bacon advocated experimental science and orderly collections of physical facts. He saw a continually changing world, and wanted to direct the changes toward utility for all men, not 'before' but 'after' the events of research. "The subtility of nature", he declared, "is far beyond that of sense or understanding", and, again, "The real legitimate goal of the sciences is the endowment of human life with new inventions and riches."

The history of the Royal Institution, when Count Rumford interested the English public in establishing it as a laboratory for research and exposition about 1800, reads also like a continuation of the plan to acquire new knowledge by the direct, efferent method, and to encourage organised methods of dispensing and utilising it. It is scarcely too much to say that, if Francis Bacon could have had the Royal Institution and Michael Faraday in mind when he tried to point the way for useful development of science, he need have foreseen no other means.

It is well for us to realise not only Faraday's natural endowment, but also his artificial environment. Under Davy, he had become equipped with the best physical knowledge of his time. Thus, when he joined the Royal Institution as assistant in the laboratory, he was like some highly sensitive, but very young, plant in a new environment perfectly suited for growth. No other position in the world afforded such an opportunity for a young man who was interested in new science. His driving motive was never an immediate commercial or technical one, but purely the inquisitive searching of the infinite possibilities of Nature. He placed the highest value on new knowledge as such. He was ever ready to fit the theory to the fact. "In knowledge," he said, "that man only is to be contemned and despised who is not in a state of transition." Keenest and most unprejudiced of observers, he was a master of method, and recorded his observations in a manner to make them of maximum usefulness to others. I would estimate as not the least of his contributions to science the way in which he wrote those notes, their fullness, even the distinctly separate and numbered paragraphs. Those seemingly simple methods must have started many a young scientific worker along the way of careful observation and orderly record.

Francis Bacon, Benjamin Thomson (who, with the support of such Englishmen as Joseph Banks, established the Royal Institution), Humphry Davy, Michael Faraday, and their followers at the Institution, form what must be called a world pioneering group. These men had human welfare in mind, and each one showed plainly that while he did not know the particular utilisations to be made of new knowledge, he was certain that service always resulted from new material facts. They worked for civilisation and for more and better types of it. They were insistent on experiment because they were anxious to be led by Nature. While accepting the value of the deductive sciences, they indicated by the successes of their undertakings that taboos, general principles, theories, and laws were largely useful through the values produced on questioning and testing them.

It is difficult to imagine now that Faraday could not foresee the great expansion which would occur in electricity. On the foundations which he laid, all the civilised countries of the world ultimately began building electrically. Electric lighting systems, power transmission systems, transportation systems, telegraph, telephone, and radio are all based on his demonstrations of the relationship between magnetic field and conductors. Here was no sudden flash of intellectual legerdemain. Rather the inspired and tireless work of a master builder. On those impregnable foundations he erected a structure of beauty and utility to which his followers may for ever add.

Developments in the United States of the researches of Faraday are not particularly different in kind from those of other civilised countries, but I can write more intelligently of them. As a nation the United States now uses as much electric energy as the rest of the world combined. It is difficult to realise that one short century ago Faraday was showing the race which had so long known lightning, animal electricity, 'static', and voltaic currents, that these, together with the new magnetically produced currents, were tokens of the same thing. Since that time, all the aluminium and much of the copper in the world has been produced by application of his magnetic induction method for current generation and in accord with his quantitative electrochemical laws. While his first dynamo was described in 1831, it took more than thirty years for appreciation of what such generated current might do technically. We credit him with both the principle of the electric motor and the dynamo or generator, because his first new electrical machine of 1831 produced electric current by the rotation of a copper disc bearing suitable brushes between the poles of the magnet, and as a motor he had forced a wire carrying current to rotate around a magnetic pole. No one supposes that Faraday foresaw the unlimited application of generator and motor which is following in orderly manner the systematic researches he performed. It is this fact which seems to me to connect him inseparably with Francis Bacon, who predicted such results of orderly scientific studies.

The present investments in the United States in the electric power and light industry are about twelve thousand million dollars. To this we must add more than five thousand million for electric railways, and another five thousand million for telephone and telegraph companies. A half million new customers are being added to light and power lines each year (in the United States), and about two thousand million dollars (400 million pounds) is received as income annually.

Even these data are an inadequate expression of value, because the yearly increment in the electric light and power field alone is more than five hundred million dollars annually (100 million pounds a year). About two-thirds of all the homes in the United States are now electrically lighted. More than twenty million houses are now 'wired'.

The value of electrical 'goods' made in the United States in 1929 exceeded two and a half thousand million dollars. In 1930 there were about seventy-five million dollars worth of incandescent lamps sold, and by 1930 there were sold about six hundred million dollars worth of electric household refrigerators.

Statistics and estimates are tiresome and prosaic. It is impossible even to mention many important electrical applications without making an unreadable list, but among those which exceeded a million units in use in 1931 are the flat irons (more than 19 millions), vacuum cleaners (9 millions), radio sets (10 millions), washing machines (7 millions), fans (3·9 millions), toasters (8 millions), percolators (6 millions), refrigerators (2·6 millions), space heaters (3·4 millions). Even such minor products as dry cells, storage batteries, and voltaic batteries were made to the value of 145 million dollars in 1929.

Thus far economy of electrical power production has risen with the sizes of individual generators, so that machines of 160 thousand kilowatt capacity have recently been made.

Probably, also, in no other line of commercial undertaking has an equal development of almost public ownership taken place. In the various electrical industries, including operating companies or 'utilities', there is wide distribution of stock, especially among the employees of the various organisations. This growing modification of participation by employees in the profits of their work is a promising evolution. There are more than 100,000 stockholders in the General Electric Company, more than 500,000 in the Telephone Company, about 675,000 in the three utilities, Cities Service, Electric Bond and Share, and Commonwealth and Southern, and about 85,000 in the Radio Corporation.

Generally speaking, lighting, which once was the major use of electric current, is being exceeded by other uses even in the average homes. There are many home devices coming into use which consume much more energy and save more human effort than lighting does. Electric heating and cooking, electric laundry and refrigeration devices are increasing in number and improving in quality, so that Faraday's utility contribution is just well under way.

Our farmers, because of their scattered or remote condition, have not been receiving much of Faraday's contribution, but 90,000 farms were connected to power lines for the first time last year. The total of electrified farms is now nearly 700,000, and this will rapidly increase because cross-country power lines are being interconnected into immense interlocking 'net works'. More than a tenth of the power is already used in States in which that particular power was not generated. The distance to which electric power may be economically sent is continually increasing.

It is not enough to confine one's self to past developments based on Faraday's work, nor is it correct to attribute every modern electrical advance to his personal researches. The world had to pass through those experiments and to others dependent upon them. But this is an occasion when there is no harm in indicating the potential values as well as the past services. Certainly the applications of electricity to the extent now seen in the United States will be exceeded and extended over the rest of the world. Thus Faraday, whatever he did, is bound to do much more as time goes on.

Then, too, the spread of electrical conceptions is not geographical alone. In the fields of science itself electricity in some form is become broadly basic. We now glibly speak of all matter being electrical, of about all phenomena being traceable in some way to electrical phenomena, and this reaches even to the processes of our nerve and muscle reflexes, our senses, and even our thinking.

It is a far cry from the first little machines of Faraday to the application of electricity to railroads, which at present so interests both England and America. From those machines, too, it seems a far cry to X-rays, to photoelectric cell applications, to the telegraph, the telephone, to radio, and to television. But we must remember in this connexion that it was Faraday himself who first demonstrated the identity of the unknown stuff we call electricity as he found it in the amber, the cat's fur, the electric eel, the voltaic cell, the lightning, and his electromagnetic fields.

We say blandly that electrical applications are certainly revolutionary, but do we realise yet that modern human revolutions are usually due to the natural desire for greater freedom from exhausting or forced physical work, and that Faraday's work has freed more slaves than any other revolution? It can apparently continue this service in ever-expanding degrees and ways. The South Sea islander who learned to want his first red loin-cloth may have killed a missionary to get it, but that is not now the general method. As men grow less and less savage they appreciate their missionaries better and better, and Faraday was supported by the intelligent part of a most advanced community. Perhaps that work will some day bring about co-operative international research institutions, in which more equitable distribution of responsibility and financial support will include the diverse benefited nations, and work be undertaken which is not, strictly speaking, the duty of any one nation to perform.

It is quite probable that the work of Faraday, supported by the Royal Institution, whose aim was discovery and disclosure of new physical facts, had much to do with the development of research laboratories all over the world. There are thousands now where there was none a century ago. Most of them, probably actuated by the motives which influenced the Royal Institution, still provide for broadcasting results of research of possible public value or interest. This was not always an obviously good policy in commercial organisations. But one can say, on looking over the past century's scientific and industrial accomplishments, that it has evidently been to the world's advantage that new scientific work in each of the civilised countries has been so generally and completely published. The completeness and accuracy, even the readability of all the publications of Faraday, set investigators a wonderful example, and science will never go back to the period when important or generally useful truth died out with the individual discoverers.

Electricity has had a marked effect on civilisation. True! Steam-engines broadened our physical and mental territories. But Faraday's researches, which were apparently at the time purely of academic importance, constituted peculiar and bold anticipatory effort. It was an attempt at appreciation of natural phenomena where the word appreciation involves extensive orderly investigations and understanding, followed by efforts at serviceable utilisation. Emulating Faraday—the experimenter—large numbers of industrial pioneers have been advancing into new electrical territory, both geographically and economically. They were probably influenced by the same kind of natural impulse which actuates all our explorers. This new activity is recorded in the modern literature of science, and is seen also in manufacturing and power developments.

The pioneer electrical spirit is evinced by the man who gathers capital to develop an extensive water-power in some remote district. There may be at the time no economic need for the power locally, and often none at any place, but such pioneers build in the faith that advance and change is continuous. It seems that new scientific knowledge does not long remain idle, and that if cheap power can be generated in some neck of the woods, then it is highly probable that worth-while uses will be made of it. In other words, the direction Faraday took into the untilled field of electric research is being pursued now by what we call hard-headed business men. They extend telephone, light, and power lines to connect countless different centres and sources, having the faith that as population increases, manufacturing expands, wants increase, and civilisation grows, they will be met by descending average costs of electric supply.

It is already evident that American factories have now been so completely electrified, that further effort at substituting motors for local steam plants or switches for endless belts is poor business. It is now more intriguing to substitute electrical devices for much of the operating and control of the machines themselves. The aim is to free the mechanical worker as much as possible. Countless electrical devices now take the place of his eyes, his ears, his hands, and his muscles. But as nothing takes the place of brains, these will be put to work in new ways. The millions of young people who now insist on getting advanced education far beyond the wildest hopes of ideal education a century ago, are bound to do for the general welfare much the same kind of useful research that Faraday did in his field; and evidently the way it is all going to work out is still as dim but certain as electric power was when Faraday's magnetic field first forced rotation on his current-carrying wire.

The Modern Electric Age in Relation to Faraday's Discovery of Electromagnetic Induction.

Prof. A. E. Kennelly,
Harvard University and Massachusetts Institute of Technology, Cambridge, Mass.

THE Faraday centenary celebrations in London in September will commemorate the discovery of electromagnetic induction by the great experimental scientific worker, Michael Faraday, one hundred years ago, in the laboratory of the Royal Institution. The principle involved in that discovery has proved of the greatest importance to the whole civilised world during the century which has since elapsed. The whole world, therefore, joins in the commemoration of an event which, in salient measure, has led up to practical electrical applications tending to interlink many nations in the conjoint use of electric power.

It may be of interest to outline very briefly the part which this discovery has taken in electrical engineering development.

Frictional or High-Tension Electricity.

Up to the year 1800, electricity was recognised only in the type that we call 'frictional', that is, capable of being produced by the mutual friction of unlike substances, and characterised by the properties of relatively high voltage, small quantity, and brief impulsive currents. Although in the year 1800 a very wide field of experimental knowledge had been developed in frictional electricity, by investigators in many countries, the number of its practical applications had proved to be very limited. Frictional electricity was hard to insulate and to control.

LOW-TENSION ELECTRICITY.

Volta's announcement, in 1800, of the discovery of low-tension electricity, associated with the contact of different metals and attendant electrochemical action, added a new chapter to the history of electrical development. The voltaic pile, as an electric source, was so different from the frictional machine or the influence machine, that it is no wonder doubts were raised, at first, as to whether voltaic electricity was really the same as frictional electricity. With frictional electricity no electric circuit seemed to be necessary, whereas with voltaic electricity a conducting circuit had to be provided. In this circuit the voltage was relatively low ; but the current produced might be relatively strong and steady. It took several decades for scientific workers to establish the voltaic battery on a firm basis of practical reliability.

Volta's name became incorporated in the list of practical electrical units by the Paris International Electrical Congress of 1881, under the unit name *volt*.

RELATIONSHIP BETWEEN ELECTRICITY AND MAGNETISM.

Up to the year 1820, electricity and magnetism were studied as separate and independent branches of science, electricity being both frictional and voltaic, while magnetism was the innate property of certain iron minerals called ' lodestones ', capable, however, of being imparted, by contact, to previously neutral steel bars or needles. In that year, however, Ørsted, of the University of Copenhagen, discovered that any wire, carrying a steady current from a voltaic battery, was capable of deflecting a magnetic needle suspended in its vicinity. Here was an interrelation between magnetism and electricity in motion, with the birth of a new branch of science—electromagnetism. Ørsted's name was incorporated among the list of magnetic units, under the title *oersted*, by the International Electrotechnical Commission (I.E.C.), at Oslo, in 1930.

Closely following upon Ørsted's discovery, came the work of Ampère, who further strengthened the link of electromagnetism between magnetism and electricity by showing that electric currents exert mutual attractions and repulsions, like magnetic poles. He succeeded in placing these electromechanical forces on a firm mathematical basis. The name *ampere* was assigned to the practical electromagnetic unit of current by the International Electrical Congress of Paris in 1881.

The work of Ørsted and Ampère opened the path of development for electromagnetic current-indicating instruments and galvanometers, which were badly needed. It also provided the starting-point for electromagnets and the electric motor, the movement of a compass needle by a current flowing in a wire being the initial step towards continuous rotation ; but much had to be invented and devised by Faraday, Wollaston, and others, before the first small electromagnetic motor was produced, embodying rotation.

THE ROYAL INSTITUTION.

The Royal Institution, made so famous by the work of Davy and Faraday, was planned and financed by Sir Benjamin Thompson, Count Rumford, in 1799, in conjunction with Sir Joseph Banks, then president of the Royal Society. Count Rumford was born at Woburn, Massachusetts, a suburb of Boston, in 1753, and studied at Harvard College. As a young man he taught in a school in a town of New Hampshire, at that time named Rumford ; but renamed Concord (the State capital) in 1763. He went to England, and after publishing scientific researches there, he was elected a fellow of the Royal Society. In 1796 he established the Rumford Medals by an endowment gift to both the Royal Society in London and the American Academy of Arts and Sciences in Boston, for conferring medals upon persons in Europe and in America, respectively, who made notable contributions to the subjects of light and heat.

It appears that Count Rumford invited Sir Humphry Davy to be the first lecturer at the Royal Institution. Sir Humphry Davy accepted the invitation, and proceeded to establish the fame of the Institution by his lectures and researches in chemistry and physics. Sir Humphry Davy, in 1813, invited Michael Faraday, then twenty-two years of age, to come to the Royal Institution as an assistant. Faraday accepted the post, and later, as we know, succeeded Sir Humphry Davy as the lecturer, researcher, and scientific head of the Institution, which his discoveries made yet more renowned.

FARADAY'S ELECTROMAGNETIC RESEARCHES OF 1831.

Faraday kept for many years, at the Royal Institution, a diary of his scientific work, which has since revealed more kinds of utility than its author may then have imagined. This diary is to be published in full as a valuable permanent appendix to the Faraday centenary celebration of the present year. It is clear from the diary that Faraday suspected there must be some interconnecting link between electricity and magnetism other than that already discovered by Ørsted in 1820. The diary records the details of the crucial experiment that caught the suspected missing link, on Aug. 29, 1831. The apparatus is virtually an elementary type of what we should to-day call a transformer, with primary and secondary windings on a solid iron ring core. On making and breaking the primary circuit, excited by a voltaic source, momentary induced currents were observed in the secondary circuit, closed through a galvanometer. This must have been regarded as an extraordinary new phenomenon at that date. The development of this discovery led on to the dynamo-electric generator.

It might naturally be supposed by any student of modern electrical engineering that the electric generator was first produced, then the electric motor, and thirdly the alternating current transformer. It would seem, however, that, historically, the order in discovery of fundamental principles was first the motor, then the transformer, and thirdly the generator.

CONTEMPORANEOUS RESEARCHES OF HENRY IN ELECTROMAGNETICS.

While Faraday was engaged upon his experiments on magnetic and electric interconnexion, in 1831, at the Royal Institution, at least one other scientific investigator was at work in the same field. Joseph Henry was born at Albany, New York, on Dec. 17, 1799, which happens to have been also the birthday of Sir Humphry Davy in 1778. Albany, some 250 km. up the Hudson River from New York City, and now the capital of New York State, was first settled in 1624, under the title of Beaverwyck. The name was changed in 1664 to Albany, in honour of the Duke of York and Albany, afterwards James II. of England. It was a centre of the fur trade and in 1800 was an active town. Henry studied at the Albany Academy, and was appointed its professor of mathematics and natural philosophy in 1826. It was a remarkable coincidence that Faraday and Henry, so remote from each other, and working under such different surroundings, should be investigating simultaneously the same field of electromagnetics. Faraday was in the Royal Institution, probably one of the best-equipped laboratories of that period, while Henry was in the schoolhouse of a remote American country town. Much time must have been required, at that date, to exchange scientific information between researchers in London and Albany, New York.

It would seem that each independently discovered, through different experimental apparatus, the production of electric currents from the excitation and de-excitation of a magnetic circuit linked with a secondary coil; but whereas Faraday recorded his observations in August 1831 and published them in November 1831, Henry did not publish his observations until July 1832.[1] The field of electromagnetics is, however, so large, and the scientific accomplishments of both these eminent pioneers was so outstanding, that there has been abundant recognition of each. The names of both Faraday and Henry have been included in the list of international electrical units, by international congresses, under the respective titles of the *farad* and the *henry*.

It is curious to note that while Faraday worked for more than fifty years in the Royal Institution, established in large measure by an American, Count Rumford, Henry worked for more than thirty years as the first secretary and director of the Smithsonian Institution, at Washington, D.C., a scientific organisation established by a legacy to the United States from James Smithson, an English chemist and a fellow of the Royal Society.

INTERMEDIATE STAGES BETWEEN THE DISCOVERY OF ELECTROMAGNETIC INDUCTION AND ITS LARGE-SCALE INDUSTRIAL UTILISATION.

Since the discovery of the fundamental principle of electromagnetic induction in 1831, it has required the intervening century to bridge the wide gap between that achievement and the existing stage of its utilisation for electric lighting and power distribution. It was necessary for physicists and mathematicians, in different countries, to place the discovery on a quantitative basis. This work, conducted by such leaders as Gauss, Joule, and Maxwell, occupied many years. All these three have had their names incorporated in the list of international electric and magnetic units.

Then there had to come the work of scientific inventors, to utilise the principles established for satisfying practical needs. Several of these great electrical inventors are still at work with us. After these had to follow a large number of financiers and business men, sufficiently persuaded of the practicability of the inventions to venture expenditure of capital upon them. Next had to be trained and equipped a corps of engineers and designers, to prepare, construct, and install the machines and apparatus in the electric transmission and distribution systems. Next in turn had to be trained an increasing army of operators, inspectors, and repair men to keep the systems in successful continuous operation.

Finally, and by no means least important, the public at large had to become acquainted with, and experienced in, the use and maintenance of the electrical apparatus placed at their disposal. This expanding process of education and training is constantly going on, and has been necessary for the industrial success of the original discovery. So, in our modern civilisation, a scientific discovery of the type here considered has to permeate the minds of millions of people in order to become an international industrial success.

IMPORTANCE OF THE HISTORY OF SCIENCE.

It is only necessary to make superficial inquiries into any important scientific discovery, such as that of Faraday in electromagnetic induction, to realise how little attention is devoted in the world's universities, colleges, and schools to the history (1) of basic science such as in mathematics and physics, (2) of applied science or engineering, and (3) of science in industrial practice. The study of the history of science is surely as worthy and important as the history study of either art, literature, or sociology. A beginning has indeed been made towards establishing university chairs in the history of science; but only a beginning. This study is fully as exacting as that of any other type of history, in regard to scholarship, training, and ability. It needs a knowledge of several languages, and each branch of science, as well as each period of the world's scientific history, demands its own group of working languages. It needs special gifts in exposition; because a historian of science who makes his story technical greatly reduces the number and the interest of his readers. As times goes on, it is to be expected that in each progressive country there will be established at least one university chair for the history of either basic or applied science. But, in all histories of electromagnetics, the date of Aug. 29, 1831, may be looked for as a red-letter day.

Faraday and Electrical Science in Russia and the U.S.S.R.

By W. TH. MITKEWICH, Polytechnic Institute, Leningrad.

FARADAY'S experimental researches in electricity and magnetism, his great discoveries and deep analysis of our physical conceptions, have produced an exceptional influence upon scientific thought throughout the world. His ideas have impressed themselves on the scientific work of all who were and are studying electromagnetic phenomena, as well as all natural phenomena that have any connexion with electricity and magnetism. All that has been done after Faraday in that domain of science is linked directly or indirectly to the fundamental ideas expressed and developed by him.

The principal idea which guided Faraday in all his works, and formed, so to say, the invariable background of his scientific thinking, was that all the interactions in Nature, and consequently also those of an electric and magnetic character, can exist only when some special physical conditions or phenomena are taking place between the interacting bodies and around them. He would not allow of the possibility of the conception of 'action at a distance' when studying and investigating any natural phenomenon. In his reasoning, he referred to Newton's authority; Newton had quite a definite opinion on that subject (see Newton's third letter to Bentley). Thus, where other physicists saw centres of forces acting at a distance, Faraday in his mind's eye saw physical lines of force traversing all space. From mathematical fictions which were used, and still continue to be used by some, Faraday's point of view leads us to a closer contact with what is actually going on. This may be considered as the first general reason for the great fruitfulness of Faraday's ideas.

The second fundamental consideration that guided Faraday's investigations and led him to a series of discoveries, was that between all the phenomena of Nature, and in particular between the phenomena of electricity and those of magnetism, there must exist some close connexion. He possessed an intuitive bent of mind that enabled him to inquire into the relationship of phenomena. He seems never to have deemed any physical relation complete in which discovery had not been made of the converse relation for which instinctively he sought. Not by chance, but by following up his general views of natural phenomena, Faraday made a hundred years ago, in 1831, his greatest discovery: he succeeded in generating the electric current by means of electromagnetic induction; this discovery is the true basis of modern electrical engineering and all the applications of electrical energy. Faraday saw from the beginning that peculiar properties of magnetic flux are manifested in the phenomenon of electromagnetic induction.

It should be stated * that the conception of the magnetic flux, as such, belongs fully to Faraday himself. Faraday was the founder of the doctrine of the physical properties of magnetic flux. Experimental methods discovered by Faraday permit us, in the right sense of the word, to feel the invisible magnetic flux as something real. Faraday was the first who showed the real existence of magnetic flux, which is of primary importance in all the manifestations of electric current; magnetic flux bearing all the energy of electric current. Faraday was the first who realised the insufficiency, the complete one-sidedness, and even the fallibility of our usual conceptions of the electric current, those conceptions being connected, owing to purely historical circumstances, with the process of movement of electrical fluids. He directed scientific research to the space round the conductor carrying the current, to that space where the energy of the electric current is located. Faraday showed his remarkable power of penetrating to the very nature of things when analysing the specific rôle of magnetic flux in electromagnetic phenomena, and particularly in the electromagnetic complex called by us the electric current flowing through a conductor. Faraday's mind was possessed more and more by this idea, which completely dominated him to the end of his scientific activity (see Faraday's "Experimental Researches in Electricity", beginning with Series XIX.).

Clerk Maxwell, the great interpreter of Faraday's ideas, accepted fully his principal points of view and developed them. Maxwell's differential equations of the electromagnetic field and the modern successes of wireless telegraphy and telephony are the direct development of Faraday's ideas. There is not a branch in the domain of electric and magnetic phenomena which was not considered and investigated by Faraday. His work in studying the properties of the electric field has proved of equal value to pure science as to technical applications of electrical energy. Faraday's discovery of the rotation of the plane of polarisation of light by magnetic action is the direct result of his line of thought; that discovery has revealed the electromagnetic nature of light and enabled Clerk Maxwell to describe the vortex motion in the magnetic field. In discovering the laws of electrolysis Faraday threw a bridge across between chemical and electromagnetic phenomena, and at the same time he laid the foundation for the conception of the atom of electricity that has led in turn to the conception of the electron. On the other hand, Faraday's studies also became the foundation of modern applied electrochemistry. In short, Faraday's work created a specific conception of natural phenomena and gave a powerful impulse to all kinds of practical applications of electrical energy, transforming entirely the general conditions in which modern mankind exists.

It is clear, of course, that the growth of new ideas arising from Faraday's scientific work, and the construction of electromagnetic machinery and other apparatus embodying these ideas, was the source in this field of the work of many other physicists and of many inventors. But it is undeniable that the whole army of those who worked theoretically and practically, and carried on Faraday's task, has been always inspired and supported by the genius of that great man. At the same time, it is undoubtedly true that many of Faraday's scientific achievements are not yet sufficiently understood and appreciated. His "Experimental Researches in Electricity" remains 'an Arabian book under seven seals' for those who, owing to the excesses of purely formal methods of investigation, have lost, in some degree, the capacity of understanding thoughts expressed in simple words. Faraday gave us the highest model of what physical thinking should be. He was a true natural philosopher. Every deviation from Faraday's method of study and analysis of physical phenomena leads to uncertain results. The roots of the modern crisis in physics must be sought to a great degree in this direction.

As noted above, Faraday's works have had a deep influence on the progress of physical thought all over the world. In particular, the discovery of electromagnetic induction of current attracted the attention of a number of Russian physicists. E. Lenz, member of the St. Petersburg Academy of Sciences, was much taken by the studies of this phenomenon. In 1834, that is three years after the discovery of electromagnetic induction

---

* W. Th. Mitkewich, "The Work of Faraday and Modern Developments in the Application of Electrical Energy" Paper read before the Second International Congress of the History of Science and Technology, London, 1931.

by Faraday, E. Lenz enunciated the relation between this phenomenon and the mechanical action of electric currents. Lenz's law is as follows:—If a constant current flows in the primary circuit A, and if, by the motion of A, or of the secondary circuit B, a current is induced in B, the direction of this induced current will be such that, by its electromagnetic action on A, it tends to oppose the relative motion of the circuits. In Lenz's law we meet with the first clear indication that in the phenomena of electromagnetic induction we have the manifestation of the conservation of energy. In the later works of Helmholtz, Sir William Thomson (Lord Kelvin), and Clerk Maxwell we have the completion of this idea. Further, in 1839, E. Lenz stated, in spite of the opinion of many of his contemporaries, that induced currents do not possess any special properties, as compared with currents of galvanic batteries. E. Lenz proved, too, the independence of the induced electromotive force of the diameter of wire and of its substance. In his numerous researches on electromagnetic apparatus, E. Lenz established a series of most important statements having an important rôle in the modern theory of dynamos. It may be mentioned that in 1844 he described the phenomenon which is called now the armature reaction, and stated clearly the principal conditions for the proper position of brushes on the commutator of a dynamo.

In 1837, M. H. Jacobi, member of the St. Petersburg Academy of Sciences, invented electroplating. In 1839 he sent some specimens of electroplate deposit to A. Humboldt and to the Paris Academy of Sciences, which bestowed on him a gold medal for his scientific inventions. In his reports and writings, dealing with this subject, M. H. Jacobi gives a detailed account of all the conditions affecting the character of deposition and shows the quantitative relations and examples of calculation, based on the laws of electrolysis discovered by Faraday. It was M. H. Jacobi, too, who pointed out the possibility of making use for electroplating of currents generated by electromagnetic induction. M. H. Jacobi studied also the theory of electromagnetic machines, in particular of electro-motors. He built a special electro-motor, by means of which in 1839 he put in motion on the Neva, against the current of the stream, a boat carrying fourteen persons. Studying the work of electromagnetic motors, M. H. Jacobi established in them the presence of the back electromotive force, which arises according to Faraday's law and is overcome by the electromotive force of the battery. Thus M. H. Jacobi originated the calculation of the energy balance in the process of transformation of electrical energy into mechanical work.

Electrical lighting was the first broad practical application of electrical energy, generated by dynamo-electric machines constructed according to principles indicated by Faraday. Many Russian scientific men and inventors, as Jablotchkoff, Lodygin, Tchikoleff, and others, were interested by this field. Much was done, especially by Jablotchkoff, whose 'candle', invented in 1876, contributed in large measure, thanks to its simplicity, to the development of electrical lighting, and was widely used in many countries, mostly in France. In 1877, Jablotchkoff patented the system of electric light distribution by means of transformers.

In the domain of dynamo construction the merits of the Russian inventor and scientist M. Dolivo-Dobrovolsky are especially to be noted. He studied the physical properties of the magnetic flux, worked out the first sufficiently perfect electro-motors with rotary magnetic field (asynchronous motors), and was the initiator of the application of three phase currents for power transmission (1887). In 1891 he took part in accomplishing the transmission of electrical energy by three phase current from Lauffen to Frankfurt, covering 175 km. This transmission line was of historical importance and was the first experiment that had an industrial significance.

Electrical discharges through gases, to which Faraday contributed with a number of his investigations, were studied by many Russian scientists (Stoletoff, Sluginoff, and others). In 1888, Prof. Stoletoff discovered the photoelectric effect.

In 1900, Prof. Lebedeff published investigations, in which he succeeded, for the first time, in observing and measuring the pressure of light, which was predicted by Clerk Maxwell's electromagnetic theory of light; this theory being, in its essence, an interpretation and a further development of Faraday's cardinal ideas.

It may be permitted to state here that electric welding by means of the electric arc originated in Russia, under the stress of general interest in the domain of practical applications of electrical energy. This method is now widely applied in the Unites States and Europe for shipbuilding, construction of dynamos, and, in general, for metallic constructions. The originators of this method were Russian engineers, Benardos (1882) and Slavianoff (1885).

In 1895, Prof. Popoff made his first experiments in the reception of electromagnetic waves, and in May of the same year he read a report to the Russian Physical Society, in which he demonstrated his receiver for wireless communication. This receiver possessed already such essential parts as a receiving antenna and ground connexion, and was similar in every way to the wireless receivers that were later applied for some years everywhere in wireless telegraphy.

Since 1918 the Government of U.S.S.R. has organised special centres for scientific research, so indispensable in connexion with the technical reconstruction of the Soviet Union. In particular, electrical research laboratories and institutions have been created in Leningrad, Moscow, Nijni-Novgorod, and so on. Out of a large number of Russian scientists working in these institutions we may name Prof. A. Joffe (the theory of disruptive discharge in insulating materials), Profs. M. Bonch-Brujevich, W. Lebedinsky, L. Mandelstam, and N. Papalexy (all working on wireless telegraphy and telephony), Profs. A. Tchernyshoff, A. Smuroff, and L. Sirotinsky (all working on high tension power transmission), Profs. A. Tolvinsky, K. Shenfer, and M. Kostenko (all working on dynamo-electric machines). The investigations of these scientists have an importance in practice, besides their purely scientific interest, as all the research institutions are linked to corresponding electrical factories. At the same time, scientists working in the U.S.S.R. on electricity in most cases are in close connexion with the technical reconstruction of the country, based on the growth of practical applications of electrical energy. During the past few years in the U.S.S.R. there have been erected a series of electric power stations and a number of power transmission lines. For example we may mention the following power stations: Volkhov, Shatura, Kashira, Shterovka, Nijni-Novgorod, Zemavtchaly (with a total power of 460,000 kw), all these stations feeding transmission lines 100 km.–150 km. in length and at 110 kv. pressure). The following power stations are in construction: Dnieper, Svir, Bobriki, Tcheliabinsk, Ivanovo-Voznessensk (with a total power of about 1,200,000 kw., including the 550,000 kw. of the Dnieper). These power stations will feed a series of transmission lines, 100 km.–250 km. in length and at a tension of 160 kv.–220 kv.

Faraday's investigations have had a wide and deep influence upon electrical science and its practical applications in Russia and the U.S.S R., in the course of the hundred years which have passed since the discovery of electromagnetic induction.

India's Debt to Faraday.

By Sir C. V. Raman, F.R.S., University of Calcutta.

THE idea of a life dedicated and consecrated to the service of humanity and involving the renunciation of personal advantages makes a powerful appeal to the mind of India. It is doubtful if, amongst men of science, a finer example of such a life could be discovered than that of Michael Faraday. His ideas and discoveries have benefited all mankind, and, in common with the rest of the world, India owes him a debt which can never be repaid. I consider it a great privilege to be allowed, on behalf of India, to offer my humble tribute of homage to the immortal soul of Faraday.

So long as seventy years ago the career and achievements of Faraday had made a profound impression in India. It is sufficient to mention the fact that, when the late Dr. Mahendra Lal Sircar in the sixties of the last century laboured to promote science in India, he adopted the Royal Institution of Great Britain as the model to follow in establishing a centre for scientific research. The Association for the Cultivation of Science, which he founded at Calcutta in 1876, is thus itself an Indian memorial in honour of Faraday. It has been the great privilege of the present writer and of his numerous collaborators from all over India to have enjoyed the unique facilities for research provided by this institution during the last quarter of a century.

Amongst Faraday's discoveries, the most significant in its theoretical implications was the magneto-optic effect known by his name. It established an experimental connexion between light and electromagnetism, and thus paved the way for the demonstration by Maxwell and Hertz that light is itself an electromagnetic influence propagated through space. But a further implication of the discovery was that the particles of matter which are disturbed during the propagation of light are capable of being influenced by a magnetic field and are therefore themselves electromagnetic in their nature. It required the labours of Larmor, Lorentz, and many others to elucidate and develop this implication of the Faraday effect. But let it be emphasised that the discovery of magneto-optic rotation by Faraday was the seed from which grew the mighty tree of the electron theory of the dispersion and scattering of light.

It was the hope that fundamental advances in knowledge would result from a study of the relation between dispersion and scattering of light that induced me to make it the principal subject of my activities during the last ten years. The hopes which inspired the work have not been unfulfilled. Incidentally, the researches it involved have had the result of taking the workers in Calcutta into other fields of work in which Faraday was also the pioneer. Amongst these may be mentioned diamagnetism, magne-crystallic action, and magnetochemistry. The scattering of light by molecules stands in close relation not only with their optical dispersion but also with their magneto-optic behaviour, and especially the magnetic birefringence exhibited by fluids. The result of computations, based on the theory of magnetic birefringence, is to indicate that the molecule of benzene, the aromatic hydrocarbon discovered by Faraday, and even more so, the molecules of naphthalene, anthracene, and so on, possess an astonishing degree of magnetic anisotropy. Experiments undertaken at Calcutta led to the discovery that the aliphatic hydrocarbons also exhibit magnetic birefringence, but this is extraordinarily *feeble*, and *negative* in sign, while the magnetic birefringence of the aromatic hydrocarbons is known to be *strong* and *positive.* The significance of this discovery is, in the first place, that the magnetic anisotropy of the aliphatic molecules is very small. In other words, the chemical difference between the two classes of organic compounds corresponds to a striking magnetic difference. In the second place, the relations between the optic and magnetic axes of the two kinds of molecules are curiously different, and this gives rise to the difference in the sign of the magnetic birefringence. Experimental studies by Mr. S. Bhagavantam of the magne-crystallic behaviour of organic solids, especially of naphthalene, anthracene, and hexamethylbenzene, gave results in striking agreement with those inferred from magneto-optical experiments with solutions of these substances.

The importance of studying magne-crystallic behaviour, both of diamagnetic and of paramagnetic substances, cannot be over emphasised. Mr. K. S. Krishnan has taken up this subject enthusiastically at the University of Dacca, and has developed very precise methods of measurement, and examined a large number of compounds both inorganic and organic. He has further attempted to correlate the magnetic results with the crystal structure of the substance wherever this is known from X-ray investigations. In the case of diamagnetic crystals, and especially of non-polar substances, we are probably justified in assuming the molecular susceptibility to be a constant characteristic of the substance. On the basis of this assumption, which admits of ready experimental test, it is possible to discuss the question whether the crystal structure assigned by X-ray workers is in accordance with the observed magnetic character of the crystal and the magnetic anisotropy of the molecule ascertained from magneto-optic experiments. It is possible, in fact, to determine what orientations of the molecules are possible within the crystal lattice which are consistent with its observed magnetic properties. This new method of crystal analysis developed by Krishnan appears to be full of promise.

The interpretation of the Faraday effect is itself at the present time not completely free from obscurity. Recent work by J. Becquerel, Ladenburg, and others indicates that we have to distinguish between two kinds of magneto-optic rotation, one associated with paramagnetic substances and the other with diamagnetic bodies. For the latter class, the theory originally suggested by Larmor indicates that the frequency of the 'Larmor precession' in the magnetic field, taken in conjunction with the known optical dispersion, determines the coefficient of magneto-optic rotation. Unfortunately for the theory, however, the observed rotation in many cases falls much short of the calculated value. It seems likely that this anomaly is connected with the known optical and magnetic anisotropy of the molecules, which is not taken into account in the Larmor theory of the Faraday effect. The consideration further suggests itself that, just as we have two kinds of Faraday effect, we should also have two kinds of magnetic birefringence in fluids. In addition to the diamagnetic type of birefringence which is already known, there should be a paramagnetic type of birefringence. Experiments made at my suggestion by Mr. S. W. Chinchalkar indicate that solutions of salts of the rare earths, such as cerium chloride, actually exhibit such an effect. How this special type of birefringence actually arises is not clear. But it seems possible that the cerium ion is optically anisotropic, and that in consequence of the magnetic moment it possesses tends to orientate in the field.

The study of the magnetic behaviour of gases and vapours is a special field of great interest in which Faraday was a pioneer. The experimental technique is very difficult, especially in the case of diamagnetic bodies where slight traces of oxygen as impurity would wholly vitiate the result. Recently the subject has attracted much interest owing to the reported discovery by Dr. Glaser of a curious anomaly at low pressures. The subject was taken up by Dr. V. I. Vaidyanathan, who showed that in all probability the Glaser effect was spurious. Further, he found that ozone and ethylene are diamagnetic gases and not paramagnetic ones as had previously been reported by other workers. Measurements were also made and reported by him for a number of other gases and organic vapours.

The question arises whether diamagnetism is purely a molecular property or whether it is also influenced by the state of aggregation of the substance. The accuracy of measurement in the case of vapours is not sufficient to enable this question to be decided for the transition from the gaseous to the liquid condition. *Prima facie* we should not expect any appreciable changes in passing from the liquid to the solid state except in the case of metallic bodies and electrically polar substances where questions of molecular association enter into consideration. In certain well-known cases, for example, that of metallic bismuth and graphite, large changes with temperature have been reported, and the susceptibility of bismuth is reduced to a very small fraction of itself on fusion. In such cases, the interesting question arises whether mechanical subdivision of the substance into a fine colloidal state would influence susceptibility. From experiments reported from Chidambaram, by Dr. V. I. Vaidyanathan, and more recently by Dr. S. Ramachandra Rao, it would seem that this is actually the case.

Closely related to the general question of dependence of diamagnetism on the state of aggregation is the problem whether the susceptibility of a liquid mixture strictly obeys the additive law in respect of the mass proportions of its constituents. In those cases where anomalies in density and other properties are known, we should expect small deviations from additivity of molecular susceptibilities. A high degree of precision in measurement is necessary to decide this question, and this has been attained by a special optical method developed at Calcutta by Mr. S. P. Ranganadham. It would seem that in certain cases, for example, water and alcohol mixtures, distinct deviations from a straight-line graph are actually obtained.

Before leaving the subject of magneto-chemistry, reference should be made to the work of two notable Indian exponents of the subject, Prof. D. M. Bose of Calcutta and Prof. S. S. Bhatnagar of Lahore respectively. The former has done extensive and valuable experimental work in tracing the relation between paramagnetic susceptibility and chemical constitution and correlating it with atomic and molecular structure. The theoretical considerations advanced by him in regard to the paramagnetism of the compounds of the transition group of elements lay emphasis on the magnetic moment derived from electron spin and yield results different from those indicated by the well-known theory of Hund. They appear to agree better with the experimental facts than the results of Hund's theory. Prof. Bhatnagar is the author of a systematic treatise on magneto-chemistry. He has devised a sensitive interference apparatus for measuring the susceptibilities of small quantities of substances, and discussed very fully the relation between chemical constitution and diamagnetic susceptibility in organic compounds.

Limitations of space do not permit detailed mention of the work of Dr. J. C. Ghosh and others in the field of electrochemistry, in which Faraday was a great pioneer. Reference may, however, be made to the subject of dielectric behaviour, which has received much attention from Indian workers. The study of light-scattering leads one very naturally to consider the question of dielectric behaviour. The birefringence shown by a gas or liquid in an electric field may be connected quantitatively with the electric polarity and anisotropy of its molecules. As was shown by the present writer with Mr. Krishnan, it is actually possible to compute the electric moment of the molecule, and even to indicate its geometric position in the molecule from such considerations. Further, the connexion between dielectric behaviour and electric birefringence indicates that in the case of viscous liquids we should expect at low temperatures or in rapidly oscillating fields a disappearance, or even reversal, in the sign of their electric double refraction. Experiments by Mr. S. C. Sircar and the present writer appear to indicate that the suggested phenomenon is actually observed. The interest of this observation lies in its furnishing a demonstration that the electric polarisation of a polar molecule is of two kinds, one arising from its deformation and the other from its orientation under the action of the field.

Faraday's Researches on Magneto-Optics and their Development.

By Prof. P. Zeeman, For.Mem.R.S., University of Amsterdam.

In connexion with the forthcoming celebration of the centenary of Faraday's greatest discovery, which predominantly has influenced our concepts of Nature and our present electrical industry, there is room in Nature for an article on magneto-optics which may also direct attention to Dutch scientific work in relation to Faraday's researches and discoveries.

On Sept. 13, 1845, Faraday found the first indication of what is now called the magnetic rotation of the plane of polarisation in transparent isotropic substances, the Faraday effect. The nineteenth series of the "Experimental Researches in Electricity" labelled the discovery "the magnetisation of light and the illumination of magnetic lines of force". His discovery showed that while the vibrations of linearly polarised light propagated parallel to the lines of magnetic force are always normal to the ray of light, the vibrations of the emergent beam make an angle with those of the incident light. The first substance giving a positive effect was Faraday's own "heavy glass"—boro-silicate of lead—which had been found by him in attempts to improve the qualities of optical glass. These investigations (1825–1829), dating from the first period of his scientific life, undertaken conjointly with Dollond and Herschel, had cost him nearly four years of precious labour, and had not led to the object aimed at, which was only attained much later by Schott and Abbe. In the brilliant discovery of a relation between magnetism and light, he now obtained the reward for all the patience and energy bestowed on this early work.

The theoretical views which guided Faraday in his experiments are given in the opening paragraphs of Series XIX. of his "Experimental Researches":

> § 2146. "I have long held an opinion, almost amounting to conviction, in common I believe with many other lovers of natural knowledge, that the various forms under which the forces of matter are made manifest have one common origin; or, in other words, are so directly related and mutually dependent, that they are convertible, as it were, one in another, and possess equivalents of power in their action. In modern times the proofs of their convertibility have been accumulated to a very considerable extent, and a commencement made of the determination of their equivalent forms."

Faraday knew what a delicate means for investigating the structure of transparent bodies we possess in the use of polarised light. Already, at the very beginning of the nineteenth century, Arago (1811) and Biot (1813) discovered the natural rotation of the plane of polarisation in quartz and other substances, and soon afterwards Brewster (1815) found the phenomena of accidental double refraction.

Faraday's arrangement may be described in his own words (§ 2150 "Exp. Res."):

> § 2150. "A ray of light issuing from an Argand lamp, was polarized in a horizontal plane by reflexion from a surface of glass, and the polarized ray passed through a Nicol's eye-piece revolving on a horizontal axis, so as to be easily examined by the latter. Between the polarizing mirror and eye-piece two powerful electro-magnetic poles were arranged, being either the poles of a horse-shoe magnet, or the contrary poles of two cylinder magnets; they were separated from each other about 2 inches in the direction of the line of the ray, and so placed, that, if on the same side of the polarized ray, it might pass near them; or if on the contrary sides, it might go between them, its direction being always parallel, or nearly so, to the magnetic lines of force. After that, any transparent substance placed between the two poles, would have passing through it, both the polarized ray and the magnetic lines of force at the same time and in the same direction."

Then comes a reference to the "heavy glass", and then in § 2152 the experiment with a positive result:

> "A piece of this glass, about 2 inches square and 0·5 of an inch thick, having flat and polished edges, was placed as a *diamagnetic* [a term used by Faraday strictly analogous to *dielectric*], between the poles (not as yet magnetized by the electric current), so that the polarized ray should pass through its length; the glass acted as air, water, or any other indifferent substance would do; and if the eye-piece were previously turned into such a position that the polarized ray was extinguished, or rather the image produced by it rendered invisible, then the introduction of this glass made no alteration in that respect. In this state of circumstances the force of the electro-magnet was developed, by sending an electric current through its coils, and immediately the image of the lamp-flame became visible, and continued so as long as the arrangement continued to be magnetic. On stopping the electric current, and so causing the magnetic force to cease, the

light instantly disappeared; the phenomena could be renewed at pleasure, at any instant of time, and upon any occasion, showing a perfect dependence of cause and effect."

Faraday then goes on making all kind of control experiments and investigating other transparent solids and a number of fluids and solutions. They all exhibited the effect, which apparently is a general property of matter. With air and other gases Faraday could not ascertain any effect. Relatively late (about 1880) H. Becquerel, and Kundt and Röntgen, by means of special appliances could demonstrate the small effect. Accurate measurements are due to Siertsema (1899) and M. de Haas.

A very large rotation in a gas was observed in 1898 by Macaluso and Corbino, when they passed plane polarised light, differing but little in frequency from that of the *D*-lines, through sodium vapour in a magnetic field, along the lines of force.

It is interesting to note what Faraday tells us in § 2182:

> "With some degree of curiosity and hope, I put gold leaf into the magnetic lines, but could perceive no effect. Considering the extremely small dimensions of the length of the path of the polarized ray in it, any positive result was hardly to be expected."

This last observation reminds us of the observations of Kundt (1884). With thin transparent films of iron, Kundt found that in a distance of 0·02 mm. the rotation already amounts to a full revolution. The exceptional position of iron (also of nickel and cobalt) as to magnetic rotation disappears if referred to the same magnetisation.

The essential difference between the natural rotation of quartz and the magnetic rotation of light was, of course, immediately ascertained by Faraday and applied in his multiple reflection method in order to increase the effects with the magnet.

In § 2224, Faraday makes the interesting remark that "the magnetic forces do not act on the ray of light directly and without the intervention of matter, but through the mediation of the substance in which they and the ray have a simultaneous existence". All future experience is in agreement with Faraday's remark.

In 1876, Dr. Kerr showed that a magnetisation of an iron mirror modifies the properties of incident polarised light.

In most cases the reflected light becomes elliptically polarised. The ellipticity is rather small, and the effect can be regarded approximately as a rotation of the plane of polarisation. The rotation of red light from the magnetically saturated mirror amounts to 23′ for iron, 21′ for cobalt, 3′ for nickel. These amounts are small but, nevertheless, would have been within reach of Faraday's means, at least for iron, if only a plane well-polished iron mirror had been at his disposal. The publication of Faraday's diary probably will give us details about this point.

A complementary phenomenon to the Faraday effect was found in 1910 by Cotton and Mouton by their discovery of the magnetic double refraction of pure liquids.

We now come to a discovery which undoubtedly would have been made by Faraday, if the times had been ripe for it. I mean the phenomena produced in spectroscopy by a magnetic field. These involve the splitting up of the lines of a line spectrum of a substance, when immersed in a strong magnetic field, each line being resolved into several components, each of characteristic frequency and characteristic polarisation and intensity. This effect has proved a most powerful means of discovering the nature of the forces in the atom.

In 1862, Faraday made the relation between magnetism and light the subject of, it is said, his last experimental work. He endeavoured, but in vain, to detect any change in the lines of the spectrum of a flame when this is under strong magnetic influence. The technique of obtaining strong magnetic fields and powerful spectroscopes was, however, inadequately worked out at the time. But in 1881 the Rowland grating was discovered, and its great resolving power enabled physicists to see details of spectra hidden to a former generation.

During several years I was occupied (for my thesis) with experimental work on the Kerr effect and studied the theories proposed to account for this phenomenon. Stimulated by the reading of Maxwell's sketch of Faraday's great life, I was able to discover in 1896 the magnetic resolution of the spectrum lines. Quite independently of a special theory, I had the idea that when the forces acting during the propagation of light in the Faraday effect were also present in a radiating flame under magnetic influence, possibly some new effect would manifest itself. It might have been otherwise indeed. At a much later date (1918) Lorentz said: "Then Zeeman could discover, as he has done, quite independently of any special theory, and without any previous consultation with myself, the magnetic resolution of spectrum lines ; he could not have succeeded, if the mass of the electrons had been ten times greater with the identical electric charge".

Indeed, guided by Lorentz's theory I made a rough determination of the specific charge at a very early stage (*Proc. Roy. Acad. Sci.*, Amsterdam, October, November, 1896), when the effect was only seen as a slight broadening of the sodium lines ; I found for the ratio of charge to mass the high value 10^7 c.g.s., quite different from the electrolytic ratio for hydrogen. I may be permitted to mention here that having come to this conclusion, I immediately went to Lorentz to tell him. He remarked : "That looks really bad ; it does not agree at all with what is to be expected".

I now propose to give a rather long quotation from an extremely interesting lecture, delivered in May 1929 to the Institute of Metals (*Jour. Inst. Met.*, vol. 41, No. 1, 1929) by Sir Oliver Lodge, entitled "States of Mind which make and miss Discoveries, with some Ideas about Metals". This paper contains several remarks of importance about metals, but still more instructive are perhaps those where Sir Oliver Lodge speaks to us as educator and philosopher. All young physicists should read his words, often expressed with deep humour, and try to formulate his lessons for themselves.

"*Zeeman's Discovery.* The Zeeman effect, too, is rather instructive from my present point of view in its incipient stages. Larmor's theory of radiation, before the era of electrons, had shown virtually that if a source of radiation were plunged in a magnetic field, the lines of the spectrum ought to be broadened, because a radiating atom would be influenced by any magnetic field in which that revolving or vibrating atom constituted an electric current. It was well known that an electric current was perturbed by magnetism, and this perturbation ought to show itself in the lines of the emitted spectrum. Instead, however, of getting an experimenter to try this with modern devices, that is, with a Rowland grating and a very strong field, Larmor—perhaps deterred by the knowledge that Faraday without theoretical clue had looked for some such effect by the aid of prisms and other inadequate devices known in his day, and had failed to find it in spite of his experimental skill—Larmor, I say, proceeded in a state of mind which I may call that of super-theoretical knowledge, to calculate quantitatively how much effect was to be expected ; i.e. how much could be expected from any reasonable field, acting, let us say, upon sodium light. He found it surpassingly small, and therefore gave up the quest. He had no idea at that time of anything smaller than an atom that was likely to radiate ; and if it were the whole atom that radiated, the effect of a magnetic field would be hopelessly small ; for theory showed that it would depend on the ratio of charge to mass, and the mass of an atom is much too big : nearly 2000 times too big.

"Zeeman, however, undeterred by super-theory and quite independently of it, proceeded to repeat Faraday's old experiment, by examining the spectrum of a sodium flame immersed in a strong magnetic field, by means of a Rowland grating. He found the effect—small indeed, but not null ; the lines were slightly broadened. Directly this preliminary observation was announced, Larmor wrote to me at Liverpool asking me to repeat Zeeman's experiment, which (having a concave Rowland grating in the cupboard and a three-inch telescope) I promptly did. In about a week I had verified it, and showed the broadening of the lines at a Royal Society soirée [May 20, 1897] immediately afterwards. By that time we knew the reason why Zeeman had succeeded, for the rough measurement admitted an estimate of the amount of broadening. The ratio of charge to mass, instead of being something under 10^3 or 10^4, came out 10^7, or about 2000 times bigger than any atom could have shown. In fact, the radiating particle, thus perturbed by the magnetic field, could not be an atom but only the charge of an atom.

"This illustrates that an experimenter should seldom be deterred by a theoretical difficulty ; for the data on which the theory is dependent *may* be erroneous. The theory mathematically may be right enough, but the data, the essential physical machinery, may be different from what had been anticipated. Zeeman's effect was observable because the radiating particle was a unit electric charge, and because the minute mass of the electron was soon afterwards brilliantly ascertained by Sir J. J. Thomson ; and so the outstanding difficulty was removed. The magnitude of Zeeman's effect, in fact, proved that the electron was the real radiator—a far-reaching discovery applicable to light of all kinds.

"Then came H. A. Lorentz, who applied his super-theoretical knowledge to an electron revolving like an electric current in a magnetic field ; and predicted that the lines should not merely be broadened but should be doubled or trebled according to the way the source of light was looked at, whether along the lines of force or across them, and further, that the lines would be polarized in certain definite fashion. Zeeman immediately proceeded to re-examine the phenomenon with still greater power, and verified every detail of Lorentz's prediction, subsequently finding out many other details about the lines—one of the sodium *D*-lines being quadrupled, and the other sextupled, for instance ; all which is now explained by a further elaborated theory, and has become part of modern physics."

In the second volume of Sir Joseph Larmor's "Mathematical and Physical Papers" we find a historical footnote concerning the beginning of the new chapter. I must resist the temptation to reproduce it here, because I want to say something about the more recent developments of the subject.

The theory of the triplication of the lines is most conveniently described by a beautiful theorem of Larmor (*Phil. Mag.*, December 1897), which affirms that the magnetic field is equivalent to a rotation. The standard triplet as foreseen by Lorentz's theory soon proved to be the exception rather than the rule. The great majority of spectrum lines are resolved into patterns with many components (as many as 21 components have been observed). The 'anomalous effect' is the collective name of all the cases of complicated resolution. When the magnetic field is increased, the anomalous effect degenerates in a remarkable manner, discovered by Paschen and Back. A rearrangement of the components takes place which, for very strong fields, ends with the standard triplet.

The general theory of these effects has a long and complicated history. Landé, on the basis of quantum theoretical results and the exact experimental data of Back, derived a formal theory culminating in a vector model. The introduction into the theory by Goudsmit and Uhlenbeck of the hypothesis that the electron is itself a magnet, made it possible to explain the anomalous effect.

The anomalous effect has proved of the utmost value in disentangling the structure of spectra. Many examples could be given, but I mention here the work done in the Amsterdam Laboratory by de Bruin on ionised potassium and ionised neon and other gases. We now can predict the anomalous effect in many cases by a formula due to Landé. This formula is remarkable because it contains different quantum numbers, but none related to the magnetic field, yet the resolution in the field comes out surprisingly well. Deviations occur, however, for the 'heavier' elements.

Bakker, working in Amsterdam, very recently published the results of experiments on the effect in the noble gas spectra in connexion with 'anomalous' coupling of quantum vectors.

The magnetic resolution has been applied to two recent physical problems. The first relates to the mechanical moment of the *nucleus* of the atom. It was shown by Pauli that in order to explain the hyperfine structure of spectrum lines, intensity variations of band spectra (Heisenberg, Hund), and related problems, it is necessary to ascribe a nuclear spin moment to the nucleus of the atom. In a strong magnetic field, the different orientations of the nucleus are exhibited by a hyperfine structure of each line of the magnetic pattern, and the spacing of the hyperfine structure immediately gives the mechanical moment of the nucleus.

The second problem relates to the question of 'forbidden' transitions between spectral terms. The resolution pattern from a transition arising by quadripole radiation is quite different from that by electrically disturbed dipole radiation. The green auroral line has been proved to be of quadripole origin by its behaviour in magnetic fields.

Jean Becquerel (1907) in Paris, afterwards in collaboration with Kamerlingh Onnes and W. J. de Haas in Leyden, and independently H. du Bois and G. J. Elias, then in Berlin, made beautiful experiments at low and extremely low temperatures on the magnetic resolution of absorption spectra of crystals of the rare earths, of their salts, and of some artificial gems.

Recently Jean Becquerel, working with W. J. de Haas in the Leyden Laboratory, at temperatures near the absolute zero, were able to give decisive proof of the existence of the paramagnetic rotation of the plane of polarisation, resolving the Faraday effect into two effects of different origin. Their curves for tysonite and xenotine illustrate admirably the existence of a saturation rotation.

A practical application of the magnetic resolution of the spectrum lines is the proof by its means of the existence of powerful magnetic fields in sunspots and of a general magnetic field of the sun, two discoveries made by Prof. G. E. Hale at Mt. Wilson. When Lorentz visited Pasadena he made a trip to Mt. Wilson, and he tells us about his impressions there: "We had a glorious sunset and enjoyed the view on the plain stretching toward the Pacific with the thousands of lights of Pasadena and Los Angeles, and when night had wholly fallen, Mr. Hubble allowed us to see in one of the giant telescopes some of the marvellous nebulæ which he is constantly examining in all their details. But the spectacle that, perhaps, impressed me most of all was the Zeeman effect in the sunspots."

Of course, no attempt has been made to make this survey complete. Attention has been directed to some of the fruits which have grown on the tree planted by Faraday. We may be sure that he would have enjoyed their development. They exhibit a richer variety than he could ever have conceived.

Dynamical Aspects of Electromagnetism.

By Prof. V. K. F. Bjerknes, University, Oslo, Norway.

SCIENCE develops side by side with a number of fundamental questions, some of which, if not all, are answered differently or even in an entirely contradictory manner by different investigators and at different periods. They return in ever-changing form; they will perhaps never get their final answers, and precisely for that reason always stimulate investigation. One such question, formulated by the natural philosophers of antiquity, is this. Is space empty or filled?

Anaxagoras and Demokritos gave opposite answers, Demokritos postulating empty space in which his atoms were free to move, Anaxagoras believing that space was full, and that the medium filling it would not prevent the motion of bodies any more than water prevents the motion of fish. When modern science began, Descartes and his school demanded the filled space. But, if perhaps not Newton himself, then at least his followers for more than a century, denied the possibility of the medium claimed by Cartesians, as its resistance would retard the motion of the celestial bodies, and spoil the harmony of the Newtonian world system. The theory of empty space and of action at a distance through it seemed to be secured for ever.

Still Young and Fresnel returned to the need for a space-filling ether-propagating light. Faraday joined them, demanding a 'dielectric medium' as a carrier of the electric and magnetic fields, which his mind's eye saw in the space between the visible bodies. Maxwell united the separate demands of Young, Fresnel, and Faraday in a single one through his electromagnetic theory of light. Finally, the experiments of Hertz brought their brilliant confirmation of the Faraday-Maxwell theory. The doctrine of an ether filling space and propagating effects which have the aspect of action at a distance, seemed to be definitely established.

The victory was not, however, a complete one. No positive theory had been given for gravitational action at a distance, and even within the domain of electromagnetism the most central question remained unanswered. It had been proved that the field produces a force, but nobody could answer the question of how the field produces the force. Faraday's suggestive idea of a tension along the lines of force combined with a mutual repulsion between them, and Maxwell's admirable mathematical transcription of this idea in his stress theory remained *ad hoc* hypotheses. Maxwell did not succeed in incorporating these dynamical views organically in the field theory contained in his equations, which would have cleared up the dynamical side of electromagnetism. To quote in his own words this fundamental defect of his theory:

> "It must be carefully borne in mind that we have made only one step in the theory of the action of the medium. We have supposed it to be in a state of stress, but we have not in any way accounted for this stress, or explained how it is maintained. . . . I have not been able to make the next step, namely, to account by mechanical considerations for these stresses in the dielectric."

This next step has not yet been taken. Electromagnetism and dynamics are interconnected in the most intimate way, but we do not know how. Concerning the importance of clearing up this question we may quote Planck ("Elektricität und Magnetismus"):

> The whole of electric and magnetic or electrodynamic phenomena constitute a self-contained unit, which is clearly separated from mechanics or the movement of material particles. . . . The final and complete fusion of these two classes of phenomena, which alone would set the crown to theoretical physics, must still be left to the future.

Other difficulties also remained, especially in connexion with optical phenomena observed on or from the moving earth. But here Einstein's 'special' theory of relativity gave a convenient means of escape, and his 'general' theory of relativity opened a new way of approaching the central problem of action at a distance, making gravitation depend upon the properties not of a space-filling medium but of space itself, or more precisely of the generalised space-time. The existence of the ether claimed by Faraday and Maxwell was denied, if perhaps not by Einstein himself at least by his most ardent followers. The problem became the development of a general field theory from the properties not of a medium filling space but of space-time itself.

The development from antiquity up to the present time thus shows oscillations like those of a pendulum between two extremes, full space and empty space. Each oscillation has been connected with some great advance in our knowledge, or in our way of formulating the fundamental questions. But no advance has been so decided that one could say if or where the oscillations would stop: at a Faraday-Maxwell ether, of which we may hope some day to know the dynamical properties, or at an Einstein space which makes this ether superfluous, if it does not perhaps ultimately identify itself with it.

For the answer to questions of this kind, namely, the power of a medium to produce action at a distance, or how a field can produce a force, the hydrodynamic phenomena discovered by C. A. Bjerknes (1825–1903)—the complex of hydro-electric and hydromagnetic phenomena—may some day become of importance. By reading as a young man the polemics which in the eighteenth century Euler had conducted in vain against the victorious theory of action at a distance, C. A. Bjerknes was inspired by ideas remarkably analogous to those of Faraday and Maxwell. Studying abroad and listening to Dirichlet's lectures on hydrodynamics at the University of Göttingen in 1855, he was struck by that result of mathematical analysis which shows that a body can move with uniform velocity through a perfect fluid without experiencing any resistance. This seemed to him to refute the fundamental argument of the Newtonians against the Cartesians, that the existence of a medium in interstellar space would necessarily retard the motion of the stars, and contradict Newton's first law of motion, that of inertia. This induced him to take up the problem which occupied him for the rest of his life: the examination of the motion of any number of bodies in a fluid, in order to see if there would or would not appear mutual influences from body to body, comparable to the actions at a distance observed in Nature.

The conditions of his life did not allow him to advance very quickly with his great problem. A quarter of a century was to pass before he was able to show experiments which gave a complete verification of his mathematical results. He never succeeded himself in working out for final publication the results of his combined mathematical and experimental investigations. For this reason his researches were not able to exert any direct influence during his own time.

The main result of his investigations may now be stated thus. When seen from the proper point of view, a moving fluid system presents during every phase of its motion a most striking and most peculiar analogy to a perfectly definite electrostatic or magnetic system. The analogy consists of two inseparably joined partial analogies, a direct geometric and an inverse dynamical one: the hydrodynamic field has identically the geometrical structure of the corresponding electrostatic or magnetic field; and it produces forces equal in magnitude but opposite in sign to those produced—in an unknown way—by this electric or magnetic field.

We can thus compare on one hand the electric or magnetic field, the internal structure of which is unknown to us, with, on the other hand, the hydrodynamic field of which, in virtue of the hydrodynamic equations, we know everything, and which we describe by vectors as familiar to us as velocity (corresponding to electric displacement or magnetic induction) and the product of velocity and density, that is, specific momentum (corresponding to electric or magnetic field intensity). From the hydrodynamic equations, or even from remarkably elementary dynamical considerations, we derive both the geometrical structure of the field and the forces produced by it. The simple hydrodynamic pressure does both, no stresses of the complicated Maxwell type being required, either for maintaining the field or for producing its forces.

C. A. Bjerknes thus succeeded in showing how Nature with the greatest ease knows how to realise a field which produces a force, though in the case discovered by him it was a force equal but opposite to the force of the analogous electrical or magnetic field. But the importance of this contrast should not be overestimated. To an acting force always belongs a reacting force, and in connected systems the kinetic energy of one part of the system may play the part of the potential energy of the other part, making the reacting force (thus a force of the same direction as that of the electric or magnetic field) that one which produces the visible motions. The analogy provided by C. A. Bjerknes also gives only a first example of deep analogies existing between the electromagnetic fields and the fields of motion in material media. Already in pure hydrodynamics a second very remarkable analogy exists, which, by generalised properties of the medium, extends practically to the whole of electromagnetism. Nobody knows how far one may proceed still further along this line, not for inventing or constructing models, but of *discovering* deep analogies between dynamics and electromagnetism. The future will show whether we can advance far enough along this road to find the bridge joining these two vast domains of physics, just as the analogy discovered by Maxwell between electromagnetic and optical phenomena led ultimately to the discovery of the bridge joining these two provinces of physical science into one great domain.

What here seems promising is the depth of the analogy discovered by C. A. Bjerknes, a depth which is proved by the fact that it contains no suppositions or hypotheses, but merely the discovered *fact*, showing that the fluid system cannot move in any other way than in full conformity with this analogy.

In spite of this universality of the analogy, the motion of a fluid system only exceptionally takes such a form that the analogy presents itself *visually* to our eyes. Such an exceptional case presents itself when the motion consists of synchronous oscillations. In that case the analogy can be illustrated by striking experiments. Pulsating bodies (that is, bodies changing volume periodically) attract each other when in the same phase, and repel each other when in opposite phase, the law of distance being that of Newton. Thus, if space be filled with a homogeneous incompressible fluid, and if atoms were pulsating all in the same phase with intensities proportional to their masses, we should have a world in which all bodies attracted each other according to Newton's law for gravitation. When both phases come into play, we have the complete analogy to the law of Coulomb, with the difference that like attract and unlike repel each other. Further, in all mutual positions, and if free to perform any kind of translational or rotational motion, oscillating bodies interact precisely as if they were electric dipoles or magnets, of which like poles attract and unlike repel. Finally, the pulsating or oscillating bodies set up in neutral bodies induced oscillations corresponding to the induced magnetism acquired by neutral bodies in the magnetic field. As a consequence of these induced oscillations and the reversed pole law, a body lighter than the fluid moves in the direction of decreasing field intensity, and a body heavier than the fluid moves in the direction of increasing field intensity, just the opposite of what the corresponding ferromagnetic or diamagnetic bodies do according to Faraday's law.

This series of experiments shows visibly both the field and the forces produced by the field, as phenomena perfectly understood in virtue of the laws of dynamics. They seem to contain a promise that we shall some day, even if the way may still be long, arrive at a corresponding understanding of the electromagnetic field and its dynamical properties.

Faraday's "Chemical Manipulation".

By Sir ROBERT ROBERTSON, K.B.E., F.R.S., and B. A. ELLIS.

CHEMISTS, in view of the immense strides which have been made in their science during the past few decades, are rather apt, unless they have delved into the historical side of the subject, to overlook the fact that much of the present-day technique was known and practised by their colleagues of a hundred years ago; indeed, in many ways their relative skill was greater then, since facilities for learning were very much less, and at the same time they themselves had to construct much of their own apparatus. The excellence of much of their work is no small tribute to their skill as craftsmen.

These thoughts devolve from the forthcoming Faraday celebrations, coupled with the fact that in 1827 Faraday published a book on "Chemical Manipulation" running into well over six hundred octavo pages; this passed in the course of fifteen years into a third edition, the text of which, however, from a variety of circumstances, differed but little from that of the original. This was somewhat unfortunate, since the intervening years were not unfruitful, particularly in the analytical field.

There is no single modern volume quite corresponding with this by Faraday, who, it is interesting to note, offered it with an apology for adding "a new work on chemistry to the many excellent productions which previously existed". Faraday described himself as an experimental philosopher, and chemistry as an experimental science involving a constant appeal to facts; as the number of these presented to us naturally is so small, it is necessary to compensate for this deficiency by experiments, which have first to be devised and then performed. The description of methods for this "mere performance" or "manipulation" is the particular *raison d'être* of Faraday's book, which was to inculcate practice, not principles, the art of experimenting and not the habit of reasoning; it was thus to serve as a supplement to all the other books.

The modern student would find the text rather wordy, whilst some of the detail would appear unnecessary and over-elaborate; the latter must largely be attributed to differences in conditions, in particular of facilities and of teaching. Nevertheless, no exception can be taken to the clearness with which the details of instructions for the use of students are set out, to the wise maxims regarding procedure and the performance of operations, with especial reference to whether they are exploratory or of a final character, to the insistence on immediate and systematic noting of experiments—in short, to the general soundness of the advice on details embodied in much of the technique of the chemical laboratory of to-day.

These features are the more remarkable when the limitations then imposed upon the experimenter are considered. Thus heating was for the most part by means other than gas, and there was no bunsen burner, though certain matter, excluded from the third edition, showed that Faraday had experimented with burners embodying an air-supply, but with limited success. There was no rubber tubing for the conveyance of water, but only such small lengths, suitable for making connexions, as could be made in the laboratory from sheet rubber. There was no Liebig condenser for distillations, although by suitable devices cooling water was used for effecting condensation of vapours. There was no wash-bottle of the modern type, no water-oven for drying precipitates, nor were there glass taps. Despite all these drawbacks, the accuracy which Faraday attained in quantitative analysis is exemplified in his research on the composition of benzene, involving weighings, combustion, and measurement of gases, the whole forming a sequence of operations, often involved but of a perfectly logical character, and in the result, of surprising accuracy.

Let us, therefore, take a hasty stroll through these century-old pages: among the points to be considered in the general lay-out of a laboratory regard must be paid to lighting; a side light is necessary for observing the action of reagents and direct sunlight for promoting many chemical effects. One chair is permissible; more might encourage persons not engaged in the laboratory operations to remain. A separate room is recommended for housing balances, for the care, testing, and use of which excellent directions are given; weights and measures must be calibrated, and the methods are carefully described.

The mouth blow-pipe was an instrument much in favour in those days, and many pages are devoted to describing the mode of obtaining an even blast, and to bending, joining, and sealing glass tubing. The effect which we now call ' correction for emergent thread ' of a thermometer was realised, but was regarded more in the light of an error than as a correction. Thermo-electric junctions were just coming in.

The subject of comminution, usually now dismissed in a paragraph or so except in books dealing expressly with rock analysis, is very fully reviewed, and special hints are supplied for powdering such diverse materials as flint, charcoal, and camphor. Simple elutriation was effected in a mortar, and the method for dividing certain metals is essentially that now used for making aluminium powder.

No practical distinction was drawn between physical and chemical solution. Variations in solubility arising from the presence of other substances were realised; tartaric acid served to prevent the precipitation of many metallic hydroxides by ammonia; oxidation was effected by nitric acid and *aqua regia*, and reduction by alcohol, sugar, and the like.

Distillation and sublimation, being essentially the same phenomenon, are described together; they were carried out in retorts or flasks. Essential oils and naphtha were distilled in a current of steam.

Reflected light was recommended for the comparison of colours or turbidities; this is used in our modern photometric methods. Various devices, described for the coagulation of such precipitates as silver chloride, barium sulphate, prussian blue are still utilised.

Special paper for filtering purposes was not manufactured ; it was necessary to search among stationers' stocks for material of suitable quality, and the advice to ' look-through ' the paper is still not always in vain. Crystallisation served for purification and for the purpose of identification by means of the goniometer; crystalline form was known to be affected by the presence of other substances in solution. Evaporation was hastened in an exhausted vessel containing sulphuric acid or other desiccating agents.

Volumetric analysis was, it must be admitted, in a somewhat primitive state at that time, being confined to simple acidimetric and alkalimetric titrations with vegetable indicators such as red cabbage, litmus, and turmeric, and a very crude form of burette, in which the thumb was used to regulate the flow of solution from a tube when inverted. It was about this period that Gay-Lussac laid the foundations of the more extended applications of volumetric methods, and, even so, it was many years before these were fully appreciated and generally adopted.

Crucibles of various forms and materials, including platinum and silver, were available; among the fluxes used were potassium carbonate (for decomposing silicates), bisulphate, borax, and, for effecting reduction, charcoal. Liebig employed tubes of potash glass in his analyses of organic bodies, and it was appreciated that the pyrolytic decomposition of vapours was favoured by increasing the surface of contact and by the presence of certain other bodies. The catalytic power of spongy platinum is also recorded, though not under that name.

The advantages of mercury as a confining medium for gases had been put forward by Priestley. The mean conditions for computing gas volumes were taken as 60° F. and 30 inches of mercury; the correction for temperature is slightly different from that in use to-day; a table is provided to correct the volume of the gas for saturation with water vapour. The manipulation of gases is very fully described, covering some eighty pages.

Of all the branches of chemistry, we are apt to look on that of micro-chemistry as belonging almost entirely to this century. To read the chapter on " Tube Chemistry " in Faraday's volume is, therefore, quite salutary, for, whilst this includes the description of ordinary test-tube work, it continues with the application of tubes to the performance of all the usual procedures of chemistry, the tubes being suitably moulded for the various purposes. Faraday called this " minute chemistry ", and it is interesting to note that despite the primitive macro-burette mentioned above, a forerunner of a modern micro-model is recorded.

It would be surprising, indeed, had Faraday neglected to consider the application of the powers of electricity to chemistry, and, though the electrical apparatus to hand at that time was simpler than to-day, it was usefully applied to the analysis of gases and to the decomposition of electrolytes; both electrical machines and voltaic cells were available in various forms.

An account of lutes and cements, rendered more necessary then by reason of the more primitive apparatus, served to facilitate the selection of that most fitted for a particular purpose; an important treatise on glass-blowing is included.

Cleanliness was insisted upon in every direction, and detailed instructions are given for cleaning mercury and all kinds of apparatus. In a series of general rules for young experimenters, the importance of entering observations immediately is reiterated; some early forms of nomograms are described. The modern chemical student who worked conscientiously through the series of exercises with which Faraday's volume concludes could face any problem with equanimity so far as actual manipulative skill was involved.

Superconductivity a Polarisation Phenomenon.

WITH the collaboration of my research associates, Messrs. A. C. Burton, A. Pitt, and J. O. Wilhelm, evidence has just been obtained that an orientation effect of some kind must be involved in the phenomenon of superconductivity in metals either directly or in its demonstration in ordinary direct current experiments.

We have been investigating the high frequency resistance of lead wires, and have found that while this resistance steadily decreased with lowering temperature, no abruptness occurred when the critical temperature of lead, 7·2° K., was reached. The experiments were carried down to 2° K. without any superconductivity discontinuity being observed. In these experiments frequencies as low as 12×10^6 per second have been used, and other experiments with lower frequencies are now in train.

The experiments show that 'the time of relaxation' of the orientation phenomenon for lead is large compared with the time period of the longest of the oscillations used, namely, 10^{-7} sec.

It seems clear that with lead maintained at the temperature of liquid helium, 4·2° K., superconductivity must appear with the application of electric fields with a frequency somewhere between 12×10^6 seconds and zero. The results obtained would seem to indicate a promising path to follow for the elucidation of the phenomenon of superconduction in metals.

Chemical Effect of a Mendelian Factor for Flower Colour.

IN a letter published in NATURE of June 27, 1931, Miss Scott Moncrieff mentions an interesting case of flower-colour inheritance in *Pelargonium*. On selfing, a rose-pink variety gave seventeen offspring like itself and three others producing salmon-pink flowers. The rose-pink petals contained the anthocyanin pigments, cyanin and pelargonin (the latter only as a trace); the salmon-pink petals, pelargonin only. That is, the dominant factor in colour inheritance causes cyanin to be formed almost entirely instead of pelargonin. This factor, therefore, as pointed out by Miss Scott Moncrieff, brings about the insertion of a hydroxyl group in the phenyl ring, which process may be regarded as one of oxidation.

Such a phenomenon as that outlined above is not necessarily limited to colour-varieties. Among the higher plants, one finds, for example, in some phyla, the dihydroxy grouping (characteristic of catechol) dominant among the compounds formed in the metabolism of aromatic substances. In others, apparently, the trihydroxy grouping (characteristic of pyrogallol) prevails. Thus, there is, on the whole, a restriction of catechol tannins to some genera and orders and of pyrogallol tannins to others. Again, in regard to the flavone pigments—compounds closely resembling the anthocyanin pigments in structure—apigenin (one hydroxyl group in the phenyl ring) is found in some genera, luteolin (two hydroxyls in the phenyl ring) in others, and so forth. Or, in regard to varieties, the ivory-flowered variety of *Antirrhinum majus* contains apigenin, the yellow-flowered, luteolin. Here, again, a difference of one hydroxyl in the structure of the molecule represents a factorial difference, as in the case of *Pelargonium*. In the flavone pigments of *Antirrhinum*, however, in contrast to the anthocyanin pigments of *Pelargonium*, the dominant factor suppresses oxidation.

It is a natural desire to interpret such Mendelian factors in biochemical terms. Such an interpretation has apparently defied the biochemist for many years. Some seventeen years ago, Willstätter had identified the anthocyanin of the type of the cornflower (*Centaurea cyanus*) as cyanin; of the pink variety, as pelargonin. To students of genetics, it is clear that here, between type and variety of *Centaurea*, there is, in all probability, one Mendelian factor. The biochemical interpretation of factors for colour is, however, part of a greater problem, namely, that of the origin of anthocyanin in the plant. Clearly defined cases of factorial differences between anthocyanin types and albino varieties have been known for many years in the sweet pea, stock, *Antirrhinum*, and other plants. Here, different varieties incapable of producing anthocyanin exist which, on crossing together, give types fully coloured with this pigment. In these well-known varieties lies the secret, as yet unrevealed, of the biochemical reactions which control the formation of anthocyanin.

From more general considerations, some suggestions may be made. Here they can only be mentioned in outline, and many subsidiary points remain unexplained. Anthocyanin pigments are found, on the whole, in flowers, fruit, young leaves, autumnal leaves, and leaves subjected to drought and injury. They are, apart from varieties such as the copper beech, not found in the normal green assimilating leaf. Two fundamental conditions are characteristic, in general, of organs producing these pigments as contrasted with those from which the pigments are usually absent.

First, in flowers, fruits, young leaves, and autumnal leaves, photosynthesis is less than in the normal leaf, or may have ceased altogether. This, as recent work on nitrogen metabolism has demonstrated, leads to hydrolysis of proteins and subsequent de-amination, with production of the residues of amino-acids, both aliphatic and aromatic. Secondly, in some of the organs quoted above, there is relatively little protection against loss of water; and, moreover, in the case of petals, fruits, and autumnal leaves, approaching separation from the parent plant and other causes render supply of water increasingly difficult. The connexion of appearance of pigment with lack of water from the soil may be very obvious. I have at the moment under observation a young plane tree, a few feet high, growing in a very dry situation. All the developing leaves are brilliantly red, giving the effect, from the distance, of a plant in flower. Such an abundance of pigment is not usual in the normal young leaf of the plane.

The deduction drawn from many observations connected with the two conditions mentioned above is that anthocyanin pigments are produced from the residues of aromatic amino-acids after de-amination. Under conditions of relative desiccation, condensation among these residues takes place with formation of anthocyanin pigments. As recently shown from the researches of Ruhland and his co-workers, de-amination of amino-acids occurs both in young leaves in active growth and in leaves in which photosynthesis has ceased; the latter state, moreover, is characteristic of petals, fruits, and autumnal leaves.

How then may such an interpretation bear on the problem of genetical factors? The aromatic amino-acids affording a benzene ring residue are phenylalanine and tyrosine. An attractive supposition to explain the presence, in one group or variety, of a *p*-hydroxy grouping (pelargonin) and, in another, of the *o*-dihydroxy grouping (cyanin) would be that dihydroxyphenylalanine is a component of some proteins. Then, by segregation, this amino-acid might be missing from the protein molecule of a variety. But, though dihydroxyphenylalanine is found in certain plants, it can scarcely be so widely distributed a component of proteins as such a hypothesis demands without hitherto being detected. Moreover, even the inclusion of this substance in the protein molecule would leave unexplained the existence of a trihydroxy grouping (delphinin).

We then fall back upon the hypothesis of oxidation as being the cause of the existence of the dihydroxy and trihydroxy groupings in condensation products from aromatic residues.

From investigations upon the oxidation of aromatic acids by Dakin and others, it would appear that, on oxidation of monohydroxy acids, a hydroxyl group is inserted in the *ortho* position to the group already in the molecule: that is, *p*-hydroxy benzoic acid is, by oxidation, converted into protocatechuic acid. Such a change may be brought about in many ways, as by hydrogen peroxide, or by a catalyst. The catechol oxidase cannot, it would appear, be connected with anthocyanin formation, since it is absent from many plants which develop anthocyanin. Any number of catalysts of the dehydrase type may be postulated which, on addition of a molecule of water and subsequent removal of two atoms of hydrogen, might insert a hydroxyl group into the benzene ring. Or the extent of oxidation in the phenyl ring resulting in cyanin or delphinin may be controlled by the reaction of the tissue before condensation takes place. Then, after condensation, there would be no further fundamental change in the anthocyanin molecule, though the colour might be modified by acid or salts. The amount of oxidation, moreover, need not be rigidly maintained, and mixtures of pigments may sometimes ensue. Or, finally, the position of insertion of subsequent hydroxyl groups may be controlled by the nature and position of the substitution groups already attached to the molecule. M. W. ONSLOW.

Cambridge, July 30.

A Hard Component of the β-Radiation of Potassium.

THE investigations made up to now on the radioactivity of potassium have brought to light a very inhomogeneous β-radiation. The absorption coefficients derived by various workers vary from 27·2 to 11·2 cm.^{2}/gm., and it is difficult from these discordant data to deduce its spectral distribution; all one can say is that the velocity of the harder component, derived from absorption measurements, is about $0{\cdot}82c$. On the other hand, the feeble activity of the element does not admit of our using any of the methods of magnetic analysis, which has already given us accurate measurements of stronger radioactive radiations.

The method recently adopted by Occhialini[1] for studying rubidium is so powerful that, by sacrificing some of its resolving power, it can be applied to potassium. Fig. 1 shows the apparatus in section. A Geiger-Müller tube-counter *C*, made of a sheet of aluminium 0·0007 cm. thick, 1·5 cm. high, and 1·5 cm. in diameter, is placed in the centre of a brass cylinder *B*, 2 cm. high and 7·2 cm. in diameter; the ends are closed with ebonite stoppers, and the air inside is exhausted to a pressure of 4 cm. of mercury. The potassium salts are spread over the inner surface of the cylinder, which is then placed in a magnetic field, the lines of force of which are parallel to the axis of the counter. The β-particles emitted are deflected in circular arcs, and can only reach the counter when their radius of curvature exceeds half the distance between the active deposit and the counter. By increasing the intensity of the field, the softer rays will be gradually eliminated, so that the derivative of the intensity curve as a function of the field gives, approximately, the spectral distribution of the β-radiation (*vide* Occhialini *l.c.*). When the field is sufficiently intense, no electron reaches the counter, so that it only records the spontaneous impulses, that is, those due to the penetrating radiation and to the radioactivity of the apparatus and its surroundings. By protecting the apparatus with a lead shield, the number of spontaneous impulses could be reduced to 1·5 ± 0·1 per minute, as found by actual experiment without the salts. The impulses were amplified by a system of thermionic valves and were recorded automatically.

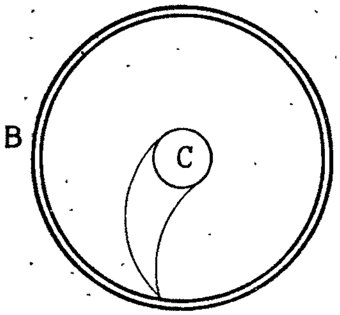

FIG. 1.

The first experiment was carried out with a thin layer of potassium chloride, about 0·014 gm./cm.^{2}, on a silver lamina. It was found that, as the field increased, the intensity, as recorded by the counter, was constant at first, and then decreased rather rapidly between 580 and 1810 gauss, showing a large number of β-rays with a velocity less than $0{\cdot}83c$. The frequency of the impulses decreased slowly with fields of still greater intensity, but even with a field of 2200 gauss, the maximum available, the frequency was sensibly greater than that of the spontaneous impulses. From this it appears that there is a component less intense but much harder associated with the known β-radiation, and that its velocity is certainly greater than $0{\cdot}90c$.

To confirm this result, the analysis of the lower end of the curve was repeated, using a thicker layer of salts, about 0·1 gm./cm.^{2}, on an aluminium plate. The results were as follow:

Field (gauss) . .	0	1870	2100	2200
Impulses/minute .	18·31 ± 0·32	7·62 ± 0·39	6·35 ± 0·35	5·80 ± 0·33

They show that the impulses recorded with maximum field exceed the spontaneous ones by more than twelve times the mean error. A layer of potassium bromide of the same thickness gave concordant results.

Although it appears to be highly improbable that the impulses observed with a field of 2200 gauss are due either to an α- or a γ-radiation, yet, to make certain, a rough absorption test was made by covering the counter with a silver leaf, 0·1 gm./cm.^{2} thick. Under these conditions, the potassium chloride gave a mean of 4·21 ± 0·2 impulses without the magnetic field and 3·64 ± 0·2 with a field of 2100 gauss. It will be noted that while the silver leaf absorbs the softer part of the β-radiation very strongly, it reduces the intensity of the component, which is not deflected by nearly one-half. The results obtained are not sufficiently accurate to determine the absorption coefficient of this radiation, but they appear to confirm very definitely that it is to be considered a β-radiation.

The probable existence of a hard component of the β-radiation of potassium has been recently put forward by Behouneck as the result of his researches on the γ-radiation of this element. The results above seem to confirm his suggestion.

I wish to express my warmest acknowledgments to Prof. Rossi, who has afforded me valuable assistance and advice in my experiments.

The Atomic Weight of Fluorine.

There is a good deal of evidence from chemical sources that the atomic weight of fluorine is greater than 19·00. In recent years the ratio of sodium fluoride to sodium chloride has been determined by McAdam and Smith,[1] who find the value 19·009. In addition, from the limiting density of silicon fluoride, Germann and Booth [2] find the value 19·010, assuming that the atomic weight of silicon is 28·06. The only work which supports the value 19·00 is that of Moles and Batuecas [3] on the limiting density of methyl fluoride. Since methyl fluoride is a difficult gas to prepare in a state of purity by the method employed by Moles, and since, moreover, his density determinations show divergences far in excess of the experimental error, we have recently carried out a redetermination of the limiting density, using the same microbalance method as that employed for xenon.[4]

Methyl fluoride was prepared by Collie's method, that is, the action of heat on tetramethyl ammonium fluoride, and after purification with potash was liquefied and fractionally distilled several times until no alteration in density could be detected on further fractionation. The balancing pressures of oxygen and methyl fluoride were then compared at two densities giving the mean ratios 1·06726 and 1·06550 for pressures of oxygen of 335·61 mm. and 156·86 mm. respectively at 21° C. On extrapolation to zero pressure the limiting ratio is found to be 1·06395, corresponding to a molecular weight of 34·046. If now we assume for the atomic weight of carbon 12·010, a value which we obtained a few weeks ago from the limiting density of highly purified ethylene, we get for the atomic weight of fluorine 19·013. It may be noted that any probable alteration in the atomic weight of carbon would make that of fluorine higher.

From our results, the compressibility coefficient $1 + \lambda$ of methyl fluoride at 21° C. is 1·00823. We can calculate the corresponding value of $1 + \lambda$ at 0° C. with a very fair degree of approximation by assuming a slightly higher coefficient of thermal expansion than that of carbon dioxide, which is well known. Such a calculation carried out on our results for ethylene gives a compressibility coefficient in excellent agreement with the accepted value. For methyl fluoride, on the other hand, we find a value 1·0109 at 0° C., in complete disagreement with the value found by Moles, namely, 1·0180, but in general accordance with those for gases of similar critical constants. It may be remarked that, even if we assume that methyl fluoride has as large a coefficient of expansion as sulphur dioxide, it would be impossible to bring our coefficient higher than 1·012. In view of the fact that the critical temperatures and pressures of carbon dioxide and methyl fluoride are 31° C. and 45° C. and 73 atmos. and 62 atmos. respectively, whilst those of sulphur dioxide are 158° C. and 78 atmos., there can be little error in the compressibility coefficient which we have calculated at 0° C. Moreover, if we calculate the coefficient of thermal expansion of methyl fluoride from Moles's value for the normal density and our value for the density at 21° C., we get the highly improbable value of 0·0042. We may say that a similar calculation applied to ethylene gives the value 0·00369 for the coefficient of expansion. We must therefore conclude that Moles's values for both the density and compressibility coefficient are far too high, though by a partial compensation of errors they lead to an atomic weight of fluorine in accordance with mass spectrograph measurements. It seems likely that Moles's gas was contaminated with a few per cent of methyl ether, an impurity which he himself recognises as being possible, but which cannot occur in our method of preparation.

There seems to us, therefore, to be strong evidence that the atomic weight of fluorine lies in the neighbourhood of 19·010 rather than of 19·000. This would appear to indicate the presence in small quantities of a higher isotope.

Acromegaly in the Far North.

The question raised by Prof. Seligman [1] tempts me to proffer some speculations which I have for some time entertained. They are drawn from the field of experimental zoology, and would not merit consideration if it were not for the circumstance that they are capable of being tested experimentally. The determination of seasonal changes in animals is closely akin to the question which Prof. Seligman propounds. I suggest that inquiry directed to elucidate the significance of the pituitary gland to functional changes which exhibit a seasonal periodicity might provide the answer. The following circumstances suggest that there may exist a close relationship between pituitary secretion and seasonal states.

(1) It is now known that the co-ordination of amphibian colour change is determined by the reflex secretion of the pituitary gland. The effective stimuli are light, temperature, and humidity—the three chief agencies through which seasonal influences presumably act upon the animal body. In addition to a hormone secreted by the pars intermedia, a second hormone secreted by the pars tuberalis of the gland now seems to be involved (Hogben and Slome, 1931) in amphibian colour change.

(2) Work in my laboratory at Cape Town recorded in a paper now in the press (Hogben, Charles, and Slome) shows that removal of the pituitary in amphibia brings about drastic retrogression of the ovaries, while injection of anterior lobe extracts produces ovulation. Thus the pituitary has the same functional relationship to the ovaries in amphibia and mammals. It was further found that perceptible retrogression of the ovaries occurs in eyeless animals. Taken in conjunction with the fact that continuous illumination stimulates egg production in fowls, there is some encouragement for the supposition that the reflex stimulation of the pituitary by light is not restricted to the secretion of the hormone or hormones which

evoke melanophore response, but that light reflexly activates secretion of the pituitary gland as a whole.

(3) Functional changes associated with seasonal periodicity in mammals are of two principal types. One is the anœstrous inactivity and partial retrogression of the gonads. The other is winter sleep, which involves a greatly reduced basal metabolism. Both these phenomena have features which are highly reminiscent of the results of removing the pituitary gland. Dr. Charles obtained some evidence that amphibia have a low basal metabolism in darkness.

On the basis of these indications and others which we obtained during the past four years at Cape Town, it had been my intention to probe more deeply into the possible significance of the pituitary in connexion with seasonal phenomena. This body of investigations has now been interrupted, and I proffer these somewhat speculative remarks for the encouragement of others who are interested in the same problems. I believe that our work provided substantial evidence that the reflex activation of the pituitary by light is not confined to the secretions which control colour change. Perhaps the prolongation of the day in the arctic regions might suggest a clue to Prof. Seligman. The growth principle of the anterior lobe involved in acromegaly is not the same substance as that which activates the ovary, nor is it the same as that which influences basal metabolism by activating the thyroid. However, it is now certain that the functional relations of at least four of the six or more hormones secreted by the pituitary gland are alike in mammals and amphibia. A comparison of the effect of continuous illumination and total darkness respectively upon growth and metamorphosis in the latter would be well worth undertaking.

Biological Effects of Cosmic and γ-Radiation.

ACTINIC rays have been an important normal factor in the environment of organisms during the course of evolution, and now it is clear that rays of another category, the cosmic rays, must be regarded as having formed part of the normal environment. It is a working assumption in all bionomical investigations that every factor in the environment must be considered in regard to its possible effect upon the life of an organism : it is also possible—or even probable—that every factor in the environment has an effect upon, or is utilised by, some organism. Hence the practical demonstration of the continuous earthly incidence of the so-called cosmic rays brings a 'new' factor into the field of biology, and its effect needs to be assessed. Since it may now be accepted that these rays are and have been continuously incident upon and in the surface layers of waters (although the degree of their penetration into sea-water has apparently not yet been determined) as well as upon the land, most organisms are, or have been in time, subjected to them, and it is reasonable to look for some biological response.

It is difficult to connect any definite biological processes with the new kind of radiation now described, but the resemblance of the cosmic rays to hard γ-radiation[1] gives us one preliminary approach to an estimation of the biological effects of these rays ; for it is known that one important effect of γ-rays is to inhibit such pathological growths as occur in mammals in cancerous tissues. The effect of the addition of γ-rays to an organism—which is exhibiting abnormal growth—suggests that possibly these rays are supplying and substituting a deficiency in that organism, and that the deficiency is some kind of ray similar to the γ-rays. The likeness of these to cosmic rays further suggests that the rays entering the earth from space may be a normal biological requirement of certain organisms, for example, mammals.

The occurrence of pathological growth in an organism, which *ex hypothesi* requires and is being subjected to a bombardment of cosmic rays, may be explained by a peculiar and pathological shielding or absorbing effect of parts or the whole of that organism.

Preliminary experiments indicate that γ-rays of such an intensity as will inhibit pathological growth, that is, as emitted from a radium needle, have little or no effect on adults or developing eggs of the few invertebrates which we have so far examined, though many more experiments are needed to provide a satisfactory basis for such an important statement. The failure of γ-rays of low intensity to affect tissues is perhaps to be expected if these rays are not markedly different from the normally incident cosmic rays. On the other hand, the simple experiment of shielding animals normally subjected to cosmic rays from these rays has not yet been tried. The occurrence, however, of animals on the sea-bottom at depths which are possibly too great to be affected by such rays[2] gives us either a natural negative experiment or an instance of adaptation to the absence of these rays comparable with that of animals living in darkness. The variation of these rays in intensity with depth may very well provide an important environmental factor in the life of aquatic animals.

Research on this new and recondite biological factor will be expensive and will require close collaboration between the biologist and physicist, but there can be little doubt that it is worth undertaking, even if it should happen that only negative results are obtained.

Mineral Content of Eyes.

IN the course of an investigation into the mineral content of vertebrate tissues, mostly human, by the spectrographic method of analysis already described in NATURE,[1] the choroids of an ox's eyes were found to contain a notable quantity of barium, the percentage in the tissue dried at 100° being estimated at nearly 1·5 ; a trace of strontium was also present. The choroids of a sheep's eyes analysed at the same time gave no indication of barium, though a trace of strontium was present.

Many analyses of parts of vertebrates' eyes have since been made and certain facts have been ascertained ; it is evident, however, that much remains to be done on these lines in extension of the work. The chief facts so far ascertained are as follows :

Human choroids and the choroids of sheep, pigs, horses, dogs, and the common commercial varieties of sea fish gave no indication of barium, neither did the choroids of calves contain the minimum amount detected by this method of analysis. Traces of strontium were nearly always present, the fishes' choroids containing more than those of the land animals.

The choroids of all the cattle, 13 in number, of three years old and upwards, so far analysed contain barium, and the quantity increased with the age of the animals ; it is present in oxen, cows, and bulls.

The barium is present in largest quantity in the choroid, but it has been detected in irises and in the dark pigment separated from the choroid by rubbing. The retinas (minus the back pigmented layer, which adheres to the choroid) contain none; they contain more phosphorus than the choroids, similar proportions of magnesium, sodium, and potassium, but less calcium and iron.

Comparing the choroids of cattle of different ages from about three to seven years, the barium, as stated above, increases with the age, and, generally, as the barium increases the quantities of sodium, potassium, magnesium, calcium, iron, and copper appear to decrease: further work on this point is necessary and we hope to obtain eyes from much older animals. The first choroids analysed came from an ox of unknown age, and they contained the largest proportion of barium so far found and the smallest quantities of the other elements named.

Zbinden [2] did not find barium in cow's milk, but the strongest barium lines do not lie in the region of the spectrum in which he worked. Messrs. Adam Hilger, Ltd., in a recent letter to one of us on another subject, state that barium has been detected in cow's milk which had turned sour in glass bottles but not in fresh milk. Barium, to our knowledge, has not previously been detected in animal tissues, and its occurrence in quantity in the choroids, etc., of cattle is all the more remarkable. We are hopeful that the work described and projected may give information bearing on the mechanism of colour vision.

The Double Lateral Line of *Lepidosiren*.

A FEW days ago when examining a small male specimen of *Lepidosiren*, one of three which I brought alive on May 1 from the island of Marajo at the mouth of the Amazon River, and which are now living in the Zoological Society's Aquarium, I noticed that it had two lateral lines on each side, one slightly dorsal to the middle of the side, the other near to the mid-ventral line. Since then I have examined more thoroughly a much larger female specimen, and have observed a few more details. The course of the sensory tubes is marked by lines of intense black, contrasting sharply with the light brown of the rest of the skin when the colour is in its pale phase. The principal lateral line, which may be described as dorso-lateral, branches out over the head into the usual three tracts, one above the eye, one between the eye and the mouth, and one below the mouth, or supra-ocular, maxillary, and mandibular. The ventro-lateral line at its anterior end anastomoses with the mandibular branches of the dorso-lateral. Each of the lateral lines is associated with short branches which are obliquely transverse to its course, but these short streaks are slightly separated from the main dorso-lateral line and dorsal to it; in the case of the ventro-lateral line, they are ventral to the line, and arise directly from it. A series of similar short oblique streaks occur on either side of the mid-dorsal line of the fish, but not a continuous line.

The description of Paraguay specimens by Sir Ray Lankester, published in 1898,[1] does not mention the lateral line, but the large figure of the entire fish which illustrates the description shows only one lateral line without branches. This is surprising, because in Lankester's paper special attention is given to a paper by E. Ehlers, published in 1894,[2] and Ehlers' paper contains a detailed description of the double lateral line in specimens from Paraguay. This description agrees very closely with that which I have given above, except that he does not mention the short streaks on either side of the mid-dorsal line of the fish, which suggest a third line of the dermal sensory system. Ehlers believed that *L. paradoxa* was a distinct species, to which some of the Paraguay specimens belonged, and in these the system of lateral lines was not distinctly recognisable. My own observations appear to constitute the first recognition of the multiple lateral line system in specimens of *Lepidosiren* from the Amazon region, and tend to confirm the opinion that there is no specific difference between the *Lepidosiren* of that region and those of the swamps of Paraguay. I am much indebted to Mr. R. H. Burne of the Royal College of Surgeons Museum for his kind help in investigating the literature of the subject.

Age of Certain Gravels in the New Forest Area.

WHILE I rejoice to learn that Mr. Burkitt and his pupils are studying the Hampshire gravels,[1] I hope he will forgive me if I question whether his letter adds materially to our knowledge of the sequence of events in this difficult area.

The separation of the gravel into two layers, with or without a sandy layer between, is of frequent occurrence throughout the district, from Stoney Cross to the coast; and often, but by no means always, the upper layer is the coarser and less stratified. Since the lower has a fluviatile aspect through a considerable range of level above the existing rivers, I infer that it belongs to a period of depression of the land, with consequent aggradation: and we can date this period by the fact that unrolled Acheulean implements have been found under the gravel. Implements found in the gravel itself are usually more or less rolled, especially perhaps those from the upper layer, but we can seldom say definitely (and certainly not at Stoney Cross or Pickets Post) from which horizon the tools come. Mousterian specimens are extremely rare, but not, I think, entirely absent.

Facts have been published [2] pointing to the erosion of the main valleys down to about 50 ft. above the present rivers in, or before, Acheulean times; but Mr. Burkitt appears to go further, and to imply that the sea on the south coast of England (and even in the Solent River as far as Hordle) had reached its present level in late Chellean times; in which case the main valleys, in such soft strata, must inevitably have followed suit. But I do not see that he offers any evidence for this, or for his second postulate of a submergence "to a depth of at least 100 ft." before Acheulean times.

Finally, his correlation of the layer of sand (*c*) at Hordle with the 100 ft. raised beach at Brighton must be received with caution, (1) because a similar layer is found in neighbouring gravels (Setley, Beaulieu Heath, etc.) up to 140 ft. O.D.; and (2) because, unless there is clear proof that the sand is marine, we must make allowance for a possible gradient of the Solent River, the mouth of which was many miles farther east.

[1] NATURE, 128, 222, Aug. 8, 1931
[2] *Proc. Prehist. Soc. E. Anglia*, pp. 23 et seq., 1923.

I was much interested in reading Mr. Burkitt's letter under the above heading,[1] since some of his conclusions coincide with those that I had formed after a study of similar deposits in the basins of the Thames and Kennet in Berkshire.[2] He suggests that implements of St. Acheul type were deposited in the gravels when the coast-line stood about 100 ft. above its present level. It is reasonable to suppose that at that time our rivers were flowing about the same height above their present beds. Gravels about 100 ft. above the present rivers occur in the Upper Thames basin and beside the Kennet, but have produced no implements. East of the Goring Gap, however, where the terrace is usually 80 ft. above the river, and is known as the Boyn Hill terrace, they are numerous.

It may be open to doubt whether these spreads are of exactly the same age, since there appears to be a slight difference in level between some of the Maidenhead gravels, and the implements that they produce vary in type. It is possible that in this region we should distinguish two distinct layers, much intermixed, at 100 ft. and 80 ft. respectively above the river. Both of these terraces, if there are two, have produced implements in large numbers, mostly of St. Acheul type, but also some that have been described as Chelles, though these are more probably ruder implements of the later industry.

In the Kennet valley a few St. Acheul implements have been found in gravel beds lying 140 ft. above the river; unfortunately it is not known at what depth these were found. It is, however, possible that they were left in hollows in a gravel bench, then 40 ft.–50 ft. above the river-level, and afterwards covered by rain-wash. A similar implement, from a corresponding level, found in a gravel-pit at Boldre in the New Forest, is in the Newbury Museum.

Unusual Lightning.

In Nature for Aug. 1, p. 189, Messrs. H. E. Beckett and A. F. Dufton describe "Unusual Lightning". From their description it appears that what they saw was the illumination of a cloud by lightning taking place inside it; the discharges were probably very high up, and went from one part of the cloud to another. Such discharges, which may perhaps be in the nature of a series of discharges through the clouds, often last a second or more and are sometimes many miles long. Lightning may take place very high up in the clouds, sometimes in the hybrid cirrus. In the 'Guildford storm' of Aug. 2, 1906, the lightning, at the time the storm crossed the South Downs, was almost entirely in the hybrid cirrus about two miles above the surface, and the thunder was quite faint even when the discharges were vertically overhead.

Another storm which occurred in the summer of 1917 seems to have resembled somewhat that seen by Beckett and Dufton. Seen from high ground near London, flames seemed to shoot up from the horizon, and a soldier on leave told a member of the staff of the Meteorological Office that it was "Haig blowing up the whole . . . line". At Bedford they thought that a violent air raid was in progress over London; and it was seen from all over the south-east of England. The actual storm was tracked down to a region about five miles to the east of the Kentish coast; the lightning was high up and the thunder faint even on the coast. The farthest points from which records came were Winchester, and Benson, Oxon, each about 130 miles away, and Husbands Bosworth, Leicestershire, about 140 miles away. Even at these distant places the lightning was noticed as something unusual; and so in a way it was—the lightning high up in the clouds lit up the hybrid cirrus plumes, which looked like flames. Most of the places from which the storm was visible were much too far off for the thunder to be audible. Beckett and Dufton seem to have seen something of the same kind, though on a smaller scale. The flame colour described by them may have been due to the distance of the storm and to the state of the atmosphere through which the light had to pass.

I am afraid that 'Flachtenblitz' is new to me, but the light of an electric discharge inside a cloud can produce all the appearances noticed by Beckett and Dufton, namely, glows which extend over the whole cloud or only over a portion of it; flashes starting at one end of the cloud and moving to the other; the flashes may occur at regular intervals of time, and may last a second or more. There is no need to suppose anything more than cloud to cloud lightning.

Conservation of Rainfall as Carbohydrates.

When a good rain falls on arid country of high temperature, the growth of plant life is truly remarkable. But in a short time this verdure loses its moisture to dry winds and hot sunshine and becomes well desiccated. A point I have not seen mentioned is that a fraction of the rainfall (which I hope to determine approximately) is locked up in carbohydrate molecules, safe from sun and wind and available for animal life. Thus, anhydrous glucose when oxidised in the body will furnish 60 per cent of its weight as water and cellulose 56 per cent. Unless this is taken into account, animal life in the desert remote from water-holes is inexplicable.

Occurrence of Dulcitol in a Red Seaweed.

The occurrence of mannitol has long been recorded in seaweeds, but, so far as the literature reveals, its distribution is confined to the brown algæ, and hitherto it has been the only representative of the sugar alcohols known to occur in the algæ. We have recently had occasion to examine extracts of the red seaweed *Bostrychia scorpioides*, which grows on the salt marsh at Blakeney Point; from this material we were able to isolate, in crystalline form, the isomeric alcohol dulcitol. As this is the first recorded observation of this substance in algæ, we are proposing to examine a number of other red algæ, with the view of determining whether they also contain dulcitol, or whether we were dealing with an exceptional case. A fuller account of the experimental work will, it is hoped, appear before long in the *Biochemical Journal*.

Research Items.

The Hadzapi or Watindega of Tanganyika.—In *Africa*, vol. 4, pt. 3, Miss D. F. Bleek describes a tribe of hunters living in the northern part of the central province of Tanganyika, near Lake Eyazi, who speak a clicking language related to the Bushman and Hottentot tongues. In physique, colouring, and physiognomy the Hadzapi are entirely different from the Bushman, for they are tall, black, and very prognathous. They live by hunting. Arrow heads are made by the men themselves from bits of iron bartered with neighbouring Bantu tribes. Paint is not worn by the men, but many showed on their faces and bodies an elementary kind of tattooing used to cure illness. For cooking their food, which consists of roots, bulbs, and fruits collected by the women, the Hadzapi use clay pots which are bought from neighbouring tribes. The sun is their god, but he is not addressed, and is feared. He makes the people well and ill as he desires. If an invalid's relatives bother the sun with prayers, he will certainly die. Most men own two wives. Girls marry at sixteen, the men a little older. There does not appear to be any initiation ceremony for young people or any marriage ceremony. Dancing and singing is part of the daily life of the men, especially when there is plenty of meat. Their dancing and singing resemble that of the Bantu more than that of the Bushmen. The sounds of the language are less difficult than those of the Hottentot and Bushmen.

Shoshonean Linguistics.—Dr. Edward Sapir has published in the *Proceedings of the American Academy of Science and Arts*, vol. 65, pts. 1-3, a sketch of the Southern Paiute language, a number of Kaibab Paiute and Uintah Ute texts, and a Southern Paiute dictionary. The Shoshonean languages, to which Paiute belongs, comprise four groups—the Plateau Shoshonean languages; Tübatulabal of south-central California; Hopi; and a group of southern Californian languages comprising the Serrano dialects, the dialects of the San Luiseño-Cahuilla branch, and the Gabrielino dialects. The differences between the groups are considerable. All these languages, taken as a whole, comprise the northernmost representatives of the Uto-Aztekan stock, which includes, besides Shoshonean, Nahuatl or Aztekan and the Sonoran or Piman languages spoken in the long stretch of country between the Mexican State of Jalisco and the Rio Gila. So far as is at present known, the Uto-Aztekan languages are not generically related to any other American group. The dialect with which Dr. Sapir deals chiefly is Kaibab Paiute of south-west Utah and north-western Arizona, Kaibab being an anglicised form of an Indian expression signifying 'mountain-lying plateau'. They belong to a number of tribes loosely grouped as Southern Paiute, Paiute belonging to the Ute-Chemehuevi branch of Plateau Shoshonean. Southern Paiute and Northern Paiute must be carefully distinguished as distinct and mutually unintelligible languages.

Breeding from Colour Varieties.—Two examples of breeding from colour varieties, of interest to students of genetics, are given in the *Avicultural Magazine* for August. On p. 209, Mr. J. C. Laidlay records breeding, from hen-pheasants that had been bred white for four generations, and a cock which was white but for some red on the breast, three, among about twenty chicks, marked like the melanistic variety, a form which has come much into notice of late years. In it the chicks are very dark in the down; if males, they assume a dark purple-and-green glossed plumage with no red, and, if females, most strikingly resemble red grouse in colour. The production of this dark form from white parents reminds one of the occasional occurrence of the proverbial black sheep among our white flocks; in neither bird nor beast is the new colour ancestral, though less abnormal than white. The other instance is in Mr. D. Seth-Smith's editorial notes (p. 235) and concerns the breeding from birds reared at the zoological gardens from a blue mutant of the Masked Love-bird (*Agapornis personata*) paired to a normal specimen. One pair have had a brood of two blues and one green, while another had four greens and one blue—rather too many recessives for Mendelian expectation, but future broods may restore the balance, though it may be mentioned that two nests last year, respectively gave two greens and one blue, and one of each colour.

Growth of the Cockle.—A. C. Stephen (*Jour. Mar. Biol. Assoc.*, **17**, No. 2, 1931) records observations on the growth of the cockle on the Scottish coast. He found on the Ayrshire coast that small cockles appear about the beginning of August, a fact which points to the breeding season being in summer and not in spring, as is usually stated. Further evidence on this point is afforded by examination of the reproductive organs, which, at Millport, appear to be ripe from about the end of July. Spawning was observed only once; cockles collected on July 1, 1930, spawned on the following day in the laboratory, but the eggs did not develop. By the end of the first autumn a few of the young cockles in the sand are 10 mm. in length, but most are less than 6 mm. The first winter ring on the shells is faint and easily overlooked; the first of the several well-defined rings is therefore not the first but the second winter ring. The first ring is seen in young specimens up to one or two years of age, but in older shells, especially if there has been any erosion, is often obliterated. The size of cockles increases regularly from high-water mark to low-water mark, due to an increased rate of growth. The scattered cockles living in the *Tellina* ground, that is, seawards of the cockle-beds proper, grow very fast.

Insect Vectors and Virus Diseases of Plants.—The first virus disease to be detected was mosaic disease of tobacco. It was discovered by Iwanowsky in 1892, and in 1901 Takami provided the earliest evidence of the insect transmission of such diseases when he showed that the mosaic disease of rice was carried from plant to plant by the leafhopper, *Nephotettix apicalis*. Since these discoveries a large and increasing number of virus diseases of plants have been made known, and, in many cases, insects have been shown to be the vectors responsible for their spread. In *Biological Reviews* of the Cambridge Philosophical Society, Vol. 6, July 1931, Dr. K. M. Smith gives a comprehensive survey of knowledge respecting these various plant viruses and the insect carriers with which they are associated. With few exceptions these vectors are sucking insects belonging to the order Hemiptera, and, among the latter, the Aphididæ are by far the most important. The single species, *Myzus persicae*, is an aphid that is now known to be associated with the spread of fourteen different viruses. The data collected together by Dr. K. M. Smith seems to point to the conclusion that a relationship, other than a merely mechanical connexion, exists between plant virus and insect vector in certain cases. Thus, there is evidence that points to the conclusion that the virus is capable of multiplying within the body of the insect. The whole subject of the nature of plant viruses, and the factors governing their transmission by means of insects, is one of great difficulty. The problem is further complicated by the fact that, in two cases, different symptoms are known to be produced in the plant by the same virus when the latter is inoculated by needle and insect respectively. This carefully prepared review of the subject, which is provided with an extensive bibliography, should be read by all interested in plant pathology.

Crust-Movements after the Tango Earthquake of 1927.—In 1929, a fourth series of levellings was carried out across the central area of the Tango (Japan) earthquake of Mar. 7, 1927. The results of this and the preceding series have been studied by Prof. C. Tsuboi (Nature, vol. 126, pp. 923-924). Nearly a year later, June-Sept. 1930, a fifth series along the same route was made and the results again examined by Prof. Tsuboi (*Tokyo Imp. Acad. Proc.*, vol. 7, pp. 234-237; 1931). Generally speaking, after the lapse of three years, the ground seems to have become nearly stable, the greatest change during the preceding year amounting to only two-thirds of an inch. Prof. Tsuboi gives two curves, one showing the changes along the route before and immediately after the earthquake, the other the total change during the three years since the earthquake. When the vertical scale in the latter curve is taken ten times that for the other, the two curves are very similar in form. The principal difference between them is in the neighbourhood of the two faults produced at the time of the earthquake. Instead of the discontinuities along the faults in the earlier curve, the later shows a sensible drag upwards along the faults, suggesting that, after the earthquake, the land-blocks on opposite sides of the faults have adhered to one another.

Articulation of Isolated Sounds.—The issue of the *Zeitschrift für Experimentalphonetik* for July 1 contains an account by Messrs C. E. Parmenter, S. N. Trevino, and C. A. Bevans, of the Phonetics Laboratory of the University of Chicago, of the methods they have adopted to determine the motions of the median outline of the mouth and throat during the articulation of isolated sounds. The head of the speaker is clamped to a board between the X-ray tube and the photographic plate, the median section of the head and the plate being at right angles to the axis of the X-ray beam. The outline of the median section of the face is secured by means of a streak of powdered barium in vaseline on the nose and lips, that of the hard palate by a strip of lead foil ⅛ in. broad pasted on it from the front teeth to the uvula. The outline of the tongue is secured by means of a fine gold-plated locket chain, one end of which is fastened to the lip and the other end swallowed by the speaker. The chain is long enough to allow about three inches of it to be tucked under the tongue. Six examples of photographs obtained are reproduced.

Mechanism of Drying.—Owing to the large number of variables concerned in the process and to the variability in condition of the material as the process advances, analytical treatment of the drying of a solid substance involves considerable difficulty. Two communications on this subject by Dr. G. Bozza are published in the issue of the *Rendiconti della Reale Istituto Lombardo di Scienze e Lettere* for the current year (parts 6-10). The errors into which previous authors dealing with this question have fallen are indicated, and complete differential equations for the process, and also those corresponding with the surrounding conditions, are deduced. For the simplest case, when the substance does not suffer deformation, and when the coefficient of diffusion remains invariable during the drying, the differential equations are integrated for non-hygroscopic materials for the two periods when the surface moisture is respectively above and below the critical proportion. In this way, quantitative relationships between the moisture content of each point of a strip or parallelepiped and the time are obtained. Methods are given for the experimental determination of the necessary coefficients, as also are the results of a large number of experiments, made in conjunction with I. Secchi, to establish the relation between the coefficient of evaporation and the air velocity, knowledge of this being necessary for the further development of the investigation.

Krypton and Xenon.—A method of extraction of krypton and xenon from liquid air residues and determinations of some physical constants of these elements are described by F. J. Allen and R. B. Moore in the July *Journal of the American Chemical Society*. The method of separation avoided the use of large gasholders and the elements were obtained in a very pure condition. Preliminary density determinations indicated that the atomic weights at present assigned to krypton and xenon are too low, in agreement with Aston's mass spectrograph results. The average density of krypton was 3·733 gm./lit., that of xenon 5·887 gm./lit., and these give, with Watson's compressibility values, the atomic weights, $\mathrm{Kr} = 83{\cdot}6$ and $\mathrm{Xe} = 131{\cdot}4$. The possible errors are $\pm 0{\cdot}2$ and $\pm 0{\cdot}3$ respectively. The boiling points were found to be: Kr, $-152{\cdot}9°$, and Xe, $-107{\cdot}1°$, in each case $\pm 0{\cdot}3°$; and the triple points were Kr ($-156{\cdot}6°$; 557 mm.) and Xe ($-111{\cdot}5°$; 600 mm.). The values for the boiling points differ from the accepted values. It is clear that a revision of the properties of these two elements is indicated.

Molecular Weight of Insulin.—Sjogren and Svedberg, in the July issue of the *Journal of the American Chemical Society*, describe a determination of the molecular weight of insulin by the ultracentrifuge method. The crystalline insulin was supplied by Dr. Jensen, of Johns Hopkins University, and had been prepared from commercial beef pancreas insulin by crystallisation. Previous studies have shown that insulin is of protein nature, giving several protein reactions, having an empirical composition resembling that of proteins, being an amphoteric electrolyte and possessing an isoelectric point and ultra-violet absorption spectrum in the same region as most of the proteins. It is now shown that insulin is stable from *p*H 4·5 to about *p*H 7, and possesses a molecular weight of 35,100; at lower and higher *p*H values its molecule disintegrates into smaller units, the process being reversible near the borders of the stability region. The constants of insulin are, within the limits of error, identical with those of egg albumin and Bence Jones protein. It is very probable that insulin is a well-defined protein, and that its physiological activity is a property of the insulin molecule itself or some special group within it.

Utilisation of Atmospheric Electric Fields.—The *Zeit. für Physik* for June 20 contains a report by A. Brasch and F. Lange of their work upon the production of high potentials. Part of this has been done in the laboratory by the method in which a battery of condensers is charged in parallel, and the connexions rapidly changed to the series arrangement. A study has already been made in this way of the most suitable forms of discharge tubes for use with high voltages, and X-rays have been produced with an exciting potential of two million volts, and hydrogen positive rays with an accelerating potential of almost a million volts. A generator is now being built which it is hoped will give a potential of seven million volts. An even more interesting part of their work has, however, been carried out on Monte Generoso, in northern Italy. The district is very liable to thunderstorms, and use has been made of the large vertical fields which then occur in the atmosphere. To do this, a collector consisting of a large number of points suitably mounted was suspended in a small valley between two peaks. The whole had to be heavily insulated, as potential differences of more than ten million volts were encountered, and at the same time, as is evident from the photographs of the installation, its construction must have called for considerable mountaineering experience. The exact magnitude of the high potentials which were obtained from the apparatus is not certain, but sparks twenty-five feet in length were measured, and the corresponding potential difference estimated to be eighteen million volts.

Radio Observations during a Solar Eclipse.—In the *New Zealand Journal of Science and Technology* for June, Dr. M. A. F. Barnett gives a summary of the results obtained by the Radio Research Committee in New Zealand during the total solar eclipse of Oct. 21 and 22, 1930, by means of radio observations. As the path of totality passed across the Pacific Ocean, the observing stations near it were necessarily limited. The results agree well with those obtained during other eclipses. Observations were made on long waves (11,500 metres), on medium waves (850 and 800 metres), and on short waves (52 to 16 metres). In most cases the transmission path crossed the line of totality. The signal strength was estimated by aural methods. The strength of the long waves between Rugby and New Zealand was increased during the eclipse period, but nothing definite was obtained from the other long wave observations. On the medium wave transmissions, an effect equivalent to a partial return to night time conditions was observed. With short waves the only eclipse effect observed was a partial return to night time conditions in a few cases of the 52-metre transmission. Test records were made of the strength and persistence of atmospherics during the eclipse, but only in a few cases was a slight increase in their strength observed. It is concluded that in general the effect of the eclipse was to produce a partial return to night-time conditions. The resultant changes in signal strength follow fairly closely the equivalent changes in the amount of solar radiation reaching the atmosphere. There are indications, however, of a slight time-lag between the effects produced and the amount of solar radiation between the transmitter and the receiver.

Astronomical Topics.

Comet Ryves, 1931 *c*.—This comet was first seen by Mr. Ryves at Zaragoza on Aug. 10; he observed it almost daily up to Aug. 17, and noted that it was growing brighter. The only observation of position made elsewhere, so far as we know, was on Aug. 14 by Prof. G. van Biesbroeck, at Yerkes, who saw a tail one degree in length.

A telegram from the U.A.I. Bureau at Copenhagen has circulated the following parabolic orbit, computed by Mr. F. E. Cunningham, which indicates that it approached the sun within seven million miles on Aug. 25; it is quite likely that it would be visible in daylight about the time of perihelion:

$$\begin{array}{rl} T & \text{Aug. } 25{\cdot}900 \text{ U.T.} \\ \left.\begin{array}{r} \omega \\ \Omega \\ i \end{array}\right. & \left.\begin{array}{l} 168^\circ\, 26' \\ 101 \quad 4 \\ 169 \quad 11 \end{array}\right\} 1931{\cdot}0 \\ \log q & 8{\cdot}8633 \end{array}$$

Ephemeris for 0 h. U.T.

It will be seen that the comet remains near the sun in the sky, and observation in a dark sky will not be possible until it has become much fainter. If the above value of the perihelion distance is correct, this comet approached the sun more closely than any other comet observed in the present century, but less closely than the great comets of 1843, 1880, 1882, 1887.

Harvard Card No. 169 gives the following observed position of Nagata's comet by Prof. G. van Biesbroeck at Yerkes Observatory:

	R.A. 1931·0.	N. Decl.	Mag.
Aug. 12 10313 U.T.	$12^h\ 17^m\ 57{\cdot}25^s$	10° 8′ 18·4″	7·5

He noted that "A sharp nucleus is visible; the round coma is followed by a broad tail visible for 25′ in position angle 110°": as the comet is moving south more slowly than the sun, the conditions for observation are improving slightly.

John Harrison's Third Time-keeper.—The *Observatory* for August contains an article on this interesting old time-piece, on which Harrison was engaged from 1740 until 1757. It has been cleaned and repaired by Commander Gould, and was restarted in March last. All the four time-pieces of Harrison will shortly be in going order; the last to be undertaken is No. 1, on which Commander Gould is now at work. Harrison evidently bestowed more care and thought on No. 3 than on No. 4, which is much smaller. Yet it was the latter that won the Government award of £20,000. No. 3 was the first time-piece that contained a bimetallic compensation; it also anticipated the modern idea of a master clock and a slave one; it consists of an inner clock that is wound every thirty seconds by an outer clock. Being intended for use at sea (though it seems never to have actually been tried there), it is controlled by two large slowly-moving balances, instead of a pendulum. All Harrison's time-pieces will live in history, from the important part they played in solving the ancient problem of finding the longitude at sea.

Another Large Reflector in America.—A Science Service *Bulletin* from Washington, D.C., dated Aug. 10, announces the successful completion of the 69-inch mirror for the Perkins Observatory of Ohio Wesleyan Observatory, Delaware. It is stated to be the first very large mirror made entirely in America; in other cases the glass had been obtained from Europe. The mirror has been figured in the works of J. W. Fecker, at Pittsburgh. The tests of figure are stated to have been satisfactory; nearly 16,000 hours of work have been spent upon it. It has a central aperture, and will be used as a Cassegrain. The mirror is 10·3 inches thick and weighs 3790 pounds.

Stainless Metals.

THE economic and mechanical advantages which result from the use of the steels and cast irons are so important that, despite their low resistance to corrosion, they are used more extensively than all other metals put together. The inevitable result of this is an enormous wastage, resulting in the expenses of replacements and, even more, of the necessity of their protection by greasing, painting, etc. Sir Robert Hadfield has estimated that the annual cost throughout the world due to corrosion amounts to more than £500,000,000. Sir Harold Carpenter, in a lecture delivered before the Royal Society of Arts (*Jour. Roy. Soc. Arts*, May 8, 1931), reviewed the whole question of stainless metals, mainly ferrous ones, both from a fundamental and from the technical points of view.

Passivity and corrosion resistance appear to be due to the formation of invisible films of oxide, and it is to Evans that the credit is due of actually isolating such films. Most of the common metals have the property of forming protective oxide skins within certain ranges of temperature, and the production of a blue oxide coat on iron is one of the ways of protecting it. Unfortunately, however, the skin thus formed on iron at ordinary temperatures is not continuous and does not, therefore, constitute adequate protection. Where, on the other hand, the film is automatically repaired, efficient protection is provided, and in some cases this condition is realised in certain alloys used at high temperatures. Passivity resulting from immersion in concentrated nitric acid, potassium chromate solution, concentrated solutions of sodium carbonate, etc., is in all cases due to the formation of such skins, which, however, afford only a temporary protection. The films produced on chromium, on the other hand, are continuous and adherent, and the addition of that metal to iron greatly increases the tendency to passivity already possessed by it. The corrosion-resisting properties of the high chromium steels are due to this fact.

Various types of stainless steel have been developed with different degrees of resistance and mechanical properties. In general, the resistance increases with the chromium content and with the homogeneity of the material. The ordinary material is least attacked in the quenched condition, and if the same degree of resistance is to be obtained in the softer, tempered state the carbon content must be reduced or the chromium increased. Unlike the normal stainless steel, the alloy with 0·1 per cent of carbon and some fourteen per cent of chromium is stainless even in the annealed condition, and may be cold-worked to a considerable extent without serious diminution of its resistance.

The addition of nickel is, for many purposes, a further improvement. Such austenitic nickel-chromium steels are, in general, more resistant to corrosion, may be cold-worked without ceasing to be stainless, have remarkable ductility and resistance to shock stresses, and possess great resistance to oxidation at high temperatures. They are used, to choose one or two typical examples, in bridge construction, in refrigerating plant, for superheated steam valves, in acid mixing tanks, bathroom and stove fittings, etc. It has not yet been found possible to produce wire of the same strength as that of the strongest carbon steel wire, or to devise a steel which will withstand hot hydrochloric acid. Resistance to acids, other than nitric, appears to be associated with nickel; and nickel-chromium steels of one kind or another can be prepared which will resist attack by cold dilute hydrochloric acid, and by both hot and cold dilute sulphuric acid.

Apart from cost, however, such materials are available for almost all ordinary, and many quite special, purposes.

F. C. T.

Death and Development.*

THE paper before us embodies a rather novel theory of growth. The author tries to show that in both animals and plants, as the germ grows up into the adult, there are periods of rapid growth separated by intervals of slow growth or, especially in plants, of complete quiescence. He maintains that there are corresponding periods of mortality—a very high death-rate being correlated with each period of rapid growth—except at the end of life when old age degeneration sets in.

A priori, there is no inherent improbability in this hypothesis, but we have a right to criticise severely the kind of evidence which is brought forward in support of it. The author himself experimented with the snail *Agriolimax*, which he reared in captivity: he cites results by numerous other workers in confirmation of his own results, such as those of Pearl on *Drosophila*, Ford on the mollusc *Spisula*, Putter on the herring, Gates on the white mouse, Quetelet and Donaldson on man. Now, the obvious objection to the manner in which these results are utilised is that the author fails entirely to discriminate between natural and accidental death. Of course it may be retorted that in the last resort every death is accidental; but there is a wide difference between death as a failure of metabolism in old age and death due to the seizure of an individual by an enemy. Pearl's experiments on *Drosophila*, the author's on *Agriolimax*, and those of Gates on the white mouse, were performed on animals kept in captivity under what appeared to the experimenters to be a close approximation to natural conditions, but in which the experimental animals were carefully guarded from the assaults of their natural enemies, and in which they were supplied with their natural food. The calculations of the death-rates in the herring, on the other hand, were based on statistical studies of the number of herring larvæ in a given area. Now, as Dr. Lebour has shown in her studies at Plymouth, the herring whilst a larva is devoured by a large number of foes to which it is immune in later periods of its life. Thus, ctenophores, medusæ, and *Sagitta* have been found gorged with herring larvæ, and at a later period haddock have been found full of post-larval herring. Death from these causes bears no analogy to the death of mice from old age after about two years of life.

Death from old age, indeed, appears to be an event unknown amongst teleostean fish. When a new fishing area such as the White Sea is opened up, fish belonging to well-known species are found which have reached a remarkable size. It is obvious that when one of the principal causes of death is the attentions of one's fellow-tribesmen, the expectation of life will increase rather than diminish with the

* "Absterben und Entwicklung". By István Szabó (Kaposvár). From "Biologia Generalis," Bd. 7, Lief. 2. (Wien und Leipzig: Emil Haim and Co.)

attainment of a great age and a correspondingly great size.

Pearl's conclusions about the natural term of life in *Drosophila* are probably broadly correct, but as he had perforce to keep his insects in confined spaces, there are certain factors incident to overcrowding which he apparently overlooked. For five or six years a skilled experimenter in my laboratory has been rearing the tadpoles of the common frog with the view of testing their reactions to certain changes in the environment. Rearing tadpoles has been a schoolboy sport since time immemorial, but the average experimenter finds that he begins with a large amount of spawn from half of which tadpoles hatch out; these steadily diminish in number as they grow older, until in the end the triumphant schoolboy points to a dozen or half a dozen young frogs as the outcome of the experiments. But in my laboratory it is now possible to start with a culture dish containing 50 tadpoles and to bring 48 successfully through the metamorphosis. Sometimes extensive mortality occurs in a particular dish; when this case is investigated it is found to be due to some chemical contamination of the water. There is no inherent reason why tadpoles should die at any stage in their growth.

It is noteworthy that marine mammals, in spite of the fact that some of them such as the fin whale attain the largest dimensions (100 ft. in length with corresponding girth) ever attained by any animal living or extinct, nevertheless have a definite limit to their growth and presumably to their lives. For it has been shown (1) that when fin whales are born they are 20 ft. in length, (2) that they attain a length of 50 ft. in about a year, (3) that the union of the epiphyses with the bodies of the vertebræ, which sets a definite limit to growth and ultimately to life, occurs when the animal is eight years old.

In conclusion, we may say that Mr. Szabó's paper is interesting and suggestive of further experiments, but that his thought needs clarifying. The probable truth contained in it is that at various stages in the life history the coming into action of new powers of development, involving very active metabolism and often a resorption of old tissues, impose such a strain on the whole of the animal economy as temporarily to weaken the constitution, and that at such periods the weaker individuals succumb to adverse environmental influences. Szabó mentions such a period of weakness in the human race at the end of the first year. Apart from the strain involved in weaning and the adaptation to a new diet, there is the strain involved in cutting the teeth. Once we ourselves had startling light thrown on this subject. When resident in Canada, we met with an American Indian woman who was the mother of numerous offspring, all of whom she nursed for the full period. But as she pathetically explained to us, "she lost them all". Further investigation revealed the fact that the infants died when one year old or thereabouts, and that the cause of death was the strain of cutting a large number of teeth at one time. The simultaneous cutting of the teeth was due to the fact that when nursing one child she was in her sixth month of pregnancy with another, and Nature could not supply sufficient food to nourish the child in the womb and at the same time develop the teeth of the suckling child: these were held back in development, with catastrophic results to the child.

As to why some germs are more vigorous than others is a question too large to be discussed in this article, but it is, in our opinion, a subject of transcendent importance both for animal and human life, and is certainly not to be explained by 'chance'.

E. W. MacBride.

Pharmacology of Thallium.

THALLIUM salts have been used chiefly as a depilatory in ringworm of the scalp in children and as a poison for the extermination of rodents. Munch and Silver have recently reviewed the literature on the use of thallium, reporting at the same time some personal experiments on its toxicity and use as a rodent poison.* The salts most usually employed have been thallous acetate or sulphate.

Thallium is extremely toxic to animals but has less action on bacteria. In acute poisoning in man and animals, there is marked interference with locomotion, paresis or paralysis of the lower limbs, loss of appetite, decreased gastric activity, emesis, diarrhœa changing to obstinate constipation, a blue line on the gums; albuminuria, nephritis, and marked respiratory depression. Death occurs from respiratory failure, the heart and circulation not being involved. Post-mortem hæmorrhages into the lungs and marked irritation of the gastro-intestinal tract have been recorded. In chronic poisoning, the kidneys and central and sympathetic nervous systems are affected, leading to pains in the muscles and nerves, changes in the endocrine organs, and loss of hair: disturbances of calcium metabolism have also been reported. The action of thallium is cumulative: elimination is slow, two to three months being required for complete removal from the body of medicinal doses.

Thallium has been abandoned for treatment of night sweats in phthisis owing to its toxicity. It is still used as a depilatory in the treatment of ringworm in children: the maximum permissible as well as minimum effective dose is 8 mgm. per kgm. body weight, but even with this dose, toxic reactions frequently occur. The lethal dose for rats and mice by oral administration and for rabbits by intravenous injection is about 25 mgm. per kgm. body weight: dogs are more sensitive, 10–15 mgm. per kgm. causing death. Rats usually die in three days after eating poisoned food: increasing the dose does not accelerate the fatal issue. Thallium is therefore a comparatively slow poison.

Poisoned bait was readily consumed by laboratory rats, but when tested in the field, prairie dogs did not consume different samples with equal avidity. The reason for the difference between different samples was not determined: presumably prairie dogs are more susceptible to foreign tastes or odours than rats; both the thallium salt and the nature of the food material with which it is mixed probably play a part in making the bait attractive.

Although thallium is as toxic to rodents as strychnine and several times more toxic than arsenious oxide or redsquill powder, Munch and Silver advise that it should not be used indiscriminately as a rat poison, owing to its extreme toxicity to human beings. Where its use is found necessary for the control of highly resistant species of rodents, such as prairie dogs or ground squirrels, which refuse strychnine bait, it should be entrusted only to those who will exercise appropriate care in handling it.

---

* "The Pharmacology of Thallium and its Use in Rodent Control." By James C. Munch and James Silver. *Technical Bulletin*, No 238. United States Department of Agriculture, Washington, D.C., 1931.

Swedish Ironfields.

TWO important monographs recently published by the Geological Survey of Sweden[*] describe the geology of two interesting Swedish ironfields. Both contain excellent English summaries.

Dr. Per Geijer in "Gällivare Malmfält" gives an excellent account of the field and its rocks and ore deposits, accompanied by a detailed map, three plates of mine plans and bore-hole sections, and 71 figures in the text. This field consists mainly of sheets of leptite and gneiss with large masses of intrusive granite, dykes from which are associated with the ores. The leptite is shown by Dr. Geijer to be highly metamorphosed lavas or shallow intrusions; the silica percentage in the leptites varies, as shown by the series of analyses, from 70 to 47 per cent. The ores are non-titaniferous magnetite, with some hæmatite. The ore is often well banded and interlaminated with apatite and granite.

Dr. Geijer again advocates the view that the ores are eruptive, and interprets the field as similar to that of Kiruna, but more highly metamorphosed. The differences between the two fields are obvious and striking, and several features are difficult to reconcile with the eruptive origin of the ores. Several of the photographs of the mines, for example, Fig. 39, p. 56, Fig. 52, p. 69, and Fig. 59, p. 87, show ore resting on a footwall fault. The 'ore breccia' consists of blocks of the country rock isolated by confluent veins of ore; and as the blocks appear in their original position, as in those exposed in the open-cut of the Hermelins mine in 1907, the ore was apparently introduced in solution and not as a molten intrusion. The low percentage of titanium and the regular banding of the ore, which occurs in places in thick bands parallel to the stratification and elsewhere interleaved with such thin layers of granite that Dr. Geijer compares them to *lit-à-lit* injection, also agree with the metasomatic formation of the ore.

That origin is established by Nils H. Magnusson for the very complex ores of the Långban mining field, which is west of Stockholm and north-east of Lake Wener. The ores, like those at Gällivare, are Pre-Cambrian. The field consists of a series of leptites, dolomites, and limestones, followed by an upper series of slates, graywackes, halleflintas, and spilites. The leptitites are altered lavas and tuffs, which have been metamorphosed by the older series of granites: a later series of granites was followed by the intrusion of sheets of diabase.

The field is famous for its very complex mineral composition and the occurrence of many rare and some endemic species. The author gives a list of 110 mineral species, to summarise their paragenesis. The minerals include a great variety of manganese silicates, with lead silicates, species containing arsenic, antimony, beryllium, boron, fluorine, etc., and native metals; sulphides are of minor importance. A new manganese amphibole, tibergite, is founded. The ores are associated with skarn, which passes through a transitional layer, the skol, into the leptite. The author shows that the primary ores are metasomatic: after their formation the country was subject to thermometamorphism by the intrusions of older granites; the skol was formed metasomatically, and at the same time as the fissure veins and subsequent filling of the vugs.

Weather Foreshadowing.

THERE is an increasing number of people nowadays who have not specialised in physics, yet possess enough knowledge of the subject to be able to understand the broad principles underlying the forecasting or —to use a more suitable word that is coming into use— the 'foreshadowing' of future weather by means of synoptic weather charts. Those who are prepared to take the trouble to do this will probably find that the value to them of the official forecasts is greatly increased.

The official forecaster's many difficulties include one which arises from the large variety and extent of country to which his necessarily brief statements must refer. The intelligent recipient of these forecasts, with some knowledge of local peculiarities of weather, can often make the adjustment to the general statement that may be necessary in order to make it apply to his own neighbourhood. If he possesses, in addition, a barograph, showing the variations of barometric pressure as a continuous curve, something can also be done to correct the forecast so as to meet unforeseen movements of anticyclones or depressions. If a depression fails to advance in the expected manner, or begins to fill up, a fall of the barometer may be checked, or even be replaced by a rise. The barograph is extremely effective in showing such changes of barometric tendency.

To meet the needs of this class of person, the Meteorological Office of the Air Ministry has issued a number of pamphlets in recent years. Two that should assist in the same direction have been added this year. They are entitled "The Fishery Barograph" (2*d.*) and "Examples of Weather Maps showing Typical Distributions of Pressure" (3*d.*) (London: H.M. Stationery Office). The "Fishery Barograph", though primarily designed to help seamen to anticipate gales, contains much information that is of general interest, for it includes notes about the behaviour of the wind and the barometer on the approach of stormy weather, and certain important but not generally known facts about the nation's wireless weather forecasts. The "Examples of Weather Maps" are taken from the larger official work entitled "The Weather Map". There is little that appears to call for criticism in either pamphlet; both fulfil their task of explaining in simple language various mysteries of meteorological method and terminology.

University and Educational Intelligence.

FROM the University of Colorado we have received a bulletin containing abstracts (of 500-1500 words each) of 108 theses for higher degrees conferred in 1930. A noteworthy feature of these abstracts is the evidence they afford of the predilection of advanced students of this university for regional studies, a circumstance attributable in part, perhaps, to the publication in 1927 of a series of university studies of local geology, botany, zoology, and social history. Of the 1930 theses, more than one-fifth were regional surveys: for example, "Colorado in the Civil War", "History of a County", "Vegetation of a Mountain in Arkansas National Park", "Microzoology of Boulder Creek", and so on.

DR. K. T. COMPTON, president of the Massachusetts Institute of Technology, has announced that the Rockefeller Foundation has appropriated the sum of 170,000 dollars for research work in physics, chemistry, geology, and biology, to be spread over a period of six years. The number of students at the Institute is the greatest in its history, with the exception of the two abnormal post-War years. It is significant that of the total number (3209), 17 per cent are post-graduate students drawn from other engineering schools and State universities. This tendency has been very marked of late years. The establishment of the loan fund of 4,250,000 dollars, by which assistance is afforded to deserving students, has been of great value; during the past year 226 students have benefited by it. The establishment of special honours courses has been so successful in such departments as have tried them, that it is permissible now for any department to establish them, leading up to a severe comprehensive examination at the end of the course. A new physics and chemistry building and a spectroscopic laboratory are now in course of erection. The main laboratory will be 300 ft. × 60 ft. and will have four stories and a basement, and the spectroscopic laboratory will be 100 ft. × 60 ft. The foundations are exceptionally heavy, more than 3000 piles having been driven for the two buildings. The spectroscopic laboratory is placed upon a mat composed of alternate layers of sand, felt, transite board, ground cork, and reinforced concrete, and it is so well insulated against changes of temperature that if the outside temperature were suddenly to change 100°, it would take the interior of the building about a month to change one degree. Plans have also been drawn for a naval tank combined with a hydraulic laboratory. This has been made possible by the generosity of Mr. J. E. Aldred.

The "Purpose of a University" is discussed in an article contributed by Prof. S. Alexander to the July-September number of *The Political Quarterly*. The work of a university cannot be divorced from its practical issues in life and it would be misleading therefore to define its purpose as the acquisition, communication, and advancement of knowledge without adding that it pursues the sciences not for their own sake alone, but also, so far as the larger part of its members are concerned, in preparation for the professions or higher occupations of life. The distinguishing mark of university studies is the pursuit in each subject, not only the older and well-established aspects but also the newer, more obviously professional —of the 'science' of the subject—meaning thereby its underlying rational principles and its relations with other subjects. In England much of the work done in universities lacks this characteristic, being such as in France or Germany is done in the lycées or the gymnasia: the student is still too much of a schoolboy or schoolgirl to entertain the true spirit of academic life and needs more than mere guidance. Admitting this immaturity of undergraduates in the early part of their university course, Prof. Alexander nevertheless inveighs against the overteaching of students as a glaring defect of our universities in general and of Oxford in particular. This sins against the ideal of a university not only by incompatibility with training the student in intellectual independence and with the cultivation of the scientific spirit, but also by engrossing time which ought to be devoted by the teacher to scientific research. The Oxford tutorial system, which has so often been held up for admiration as a model of university teaching, has, in his eyes, become a positive evil; and he holds that the new studies of the natural sciences are fortunate in that the system has not taken root strongly in them. To it he ascribes Oxford's failure to keep its place in the front rank of the advancement of science: nor is there, he says, any sufficient evidence that the over-taught undergraduates of Oxford are better fitted for the work of life than those of Cambridge who have not been so tutored.

Birthdays and Research Centres.

Aug. 30, 1871.—The Right Hon. Lord **Rutherford of Nelson**, O.M., F.R.S., past president of the Royal Society; Cavendish professor of experimental physics, University of Cambridge; and chairman of the Advisory Council of the Department of Scientific and Industrial Research.

For many years, I have been engaged in researches to throw light on the structure of atomic nuclei. Several lines of attack on this problem are being actively pursued by different workers in the Cavendish Laboratory, including the determination of isotopes, the artificial disintegration of elements by α-particles, measurement of the wave-length of γ-rays, and the effect of high frequency γ-rays on the nucleus. At the moment my co-workers and I are studying in detail with the aid of new counting methods the groups of long range α-particles—about one in a million of the main group—expelled from certain radioactive substances. There is strong evidence that these rare groups of particles are closely connected with the emission of γ-rays. In an excited nucleus it is supposed that some of the α-particles are raised to a high level of energy. The majority fall back to a lower level, emitting γ-rays in the process, but in the short time before this happens a few of the α-particles are able to escape through the potential barrier and issue as long range α-particles. By a study of these particles, it is hoped to account for the origin of the γ-rays and their complicated spectrum.

In order to increase our knowledge of artificial disintegration of atoms and for other investigations, it is desirable to have available for laboratory purposes sources of high speed atoms and electrons. It is of first importance that the best method of generation of very high voltages for this end and their application to produce swift particles should be actively investigated.

Sept. 1, 1877.—Dr. F. W. **Aston**, F.R.S., fellow of Trinity College, Cambridge, and Nobel laureate for chemistry (1922).

One of the problems I have been attacking with my mass-spectrograph is the photometrical determination of the relative abundances of the isotopes of complex elements. During this investigation atomic weights have been checked and many new species of atoms discovered. Work has advanced sufficiently far to show that there is little hope of discovering any simple laws connecting these ratios of abundance. I am also making experiments on possible improvements to the apparatus to increase the accuracy of its determination of atomic masses even further. Theoretical investigators of the structure of nuclei ask for an accuracy of 10^5 and I have every hope that in the near future this will be approached.

The crying need in this work is a means of obtaining and controlling really intense beams of high speed positive ions. I hope that all engaged in research in this field will bear this in mind and neglect no byway likely to lead towards this end.

Sept. 2, 1877.—Prof. F. **Soddy**, F.R.S., professor of chemistry in the University of Oxford and Nobel laureate for chemistry (1921).

I have this year re-determined the rate of growth of radium from uranium. The attempts directly to prove that radium is a product of uranium began simultaneously with those, immediately successful, to detect the production of helium from radium. But, owing to ionium intervening, the growth proceeds according to the square of the time and is infinitesimal for the first few years. Four uranium preparations, purified from radium and ionium a quarter of a century ago, now have from 10^{-9} gm. to 10^{-10} gm. of radium, as much as it is convenient to measure accurately, and they give a very consistent value for the product of the periods of the average lives of ionium and radium, namely, $2{\cdot}44 \times 10^8$ $(\text{years})^2$.

"Money *versus* Man", published this year, gives a popular account of my theory of virtual wealth—a slight but upsetting modification of the quantity theory of money—and of the problems which confront civilisation owing to the growth of the physical sciences.

I have also applied for a patent for a form of centrifugal reversing and reducing mechanism which I am hopeful will one day find application to turbine-propelled vessels.

Sept. 3, 1882.—Dr. W. L. Balls, F.R.S., chief botanist of the Egyptian Ministry of Agriculture, and formerly chief of the Experimental Department, Fine Cotton Spinners' and Doublers' Association, Bollington, Cheshire.

A slow development of technological research on spinning quality is taking place concurrently with the isolation, testing, propagation, renewal, and bulk control of pure lines of Egyptian cotton, which occupies much of the time of my staff at Cairo, but my chief personal interest is subterranean, developed from my pre-War studies of the root and its environment. In the Templeton observation-pits we have watched sequences of events and then found them in the open field; roots growing a metre a month and remaining alive for months after the plants had been uprooted; colour changes in soil round the roots demonstrating chemical stages of deterioration through water-logging and re-aeration. We now use the crops as indicators of soil structure, and are interested in the development of aerial survey repeated through a full rotation of crops, with reference to drainage projects. At the moment I am writing up water-table observations which have accumulated on our experimental farm at Giza since 1909.

Societies and Academies.

Paris.

Academy of Sciences, June 29.—The president announced the death of Friedrich Becke, *Correspondant* for the Section of Mineralogy.—**A. Lacroix**: New observations on the tectites of Indo-China. Discussion of their origin. From the examination of a large number of fresh specimens it is concluded that the tectites result from the vertical fall of fused material possessing a high temperature. This agrees with the hypothesis of a meteoric origin of the tectites.—**Emm. de Margerie**: The last sheets of the *Carte Générale Bathymétrique des Océans* (*Panneau du Pôle Nord*).—**Paul Montel**: Functions of several linearly dependent variables.—**E. Kogbetliantz**: New observations on the orthogonal system of Hermite polynomials.—**Lucien Féraud**: Completely stable systems in the neighbourhood of an equilibrium point.—**H. Guillemet**: The evolution of the wake behind an obstacle for small values of Reynolds's number.—**Mme. V. Popovitch-Schneider**: The extension of Hele-Shaw's method to cyclic movements. The results of the experiments, in spite of the wall effect due to the small dimensions of the apparatus, show good agreement with theory. Four reproductions of photographs accompany the paper.—**Emile Bélot**: The double origin of the small planets and their emission by the rings and vortices of the large planets.—**Louis Gérard**: Reflection on a moving mirror and relativity.—**A. Damiens** and **L. Domange**: An electric furnace made of fluorspar. Details of construction of an electric tube furnace in which the inner tube is made of fluorspar. It permits of working with fluorine or hydrofluoric acid at a temperature of 1000° C.—**B. Decoux**: A piezoelectric quartz frequency meter with synchronous modulation. The meter described is transportable and is capable of high accuracy. It can also be used as a stable receiver by using the apparatus as a heterodyne.—**P. Fleury**: A precision luxmeter with homochrome regions.—**Léon** and **Eugène Bloch**, **F. Esclangon**, and **P. Lacroute**: The observation of the Zeeman effect with high frequency. High frequency discharges in rarefied gases, already proved to be of great service for the production and separation of higher order spectra, can also be utilised with advantage for the study of the Zeeman effect. The results of experiments with neon and with mercury (field 26,250 gauss) are given.—**D. Malan**: The absorption spectrum of oxygen at high temperatures. This work was undertaken with the view of detecting the formation of ozone in oxygen at a high temperature. At 1400° C. no ozone could be detected by the absorption method, and it is concluded that unless the absorption of ozone is diminished at the high temperature, the quantity of ozone produced, if any, must be very small.—**P. Daure** and **A. Kastler**: The Raman effect in some gases. The gases studied were hydrogen, acetylene, cyanogen, and steam.—**François Reymond** and **Tcheng da tchang**. The separation of polonium and of protactinium fixed on tantalum oxide. To the tantalic acid gel in solution in hydrofluoric acid some selenious acid is added, followed by sulphuric acid and sodium bisulphite. The reduced selenium produced by boiling carries down with it the whole of the polonium present.—**F. Bourion** and **E. Rouyer**: The cryoscopic study of paraldehyde in solutions of lithium chloride and magnesium chloride.—**Francis Perrin**: Molecular association and the optimum for fluorescence of solutions. The influence of salts.—**Maurice Curie** and **M. Prost**: The radiation accompanying the hydration of quinine sulphate. In water vapour at the pressure of 1 mm. the path of the radiation is about 1 mm.; at atmospheric pressure the path would be of the order of 0·001 mm.—**Mlle. Sabine Filitti**: The determination of the charge of the micelle. It is possible to determine the granular charge of a non-ionised colloid of known micellary weight by measuring the fall of *p*H produced in the dispersing medium by a given mass of dissolved substance.—**P. Mougnaud**: The estimation of fluorine. A detailed examination of the methods of Rose and of Carrière and Rouanet. The latter is rejected as inaccurate; the former is capable of improvement.—**Mlle. M. L. Delwaulle**: The action of hydrogen upon potassium permanganate.—**P. Carré** and **P. Mauclère**: The chloride of acid ethyl sulphite and the neutral mixed alkyl sulphites. The observation of Michaelis and Wagner on the production of $(C_2H_5O)\,SO.Cl$ by the interaction of neutral ethyl sulphite and phosphorus pentachloride, with subsequent separation by distillation, is shown to be inaccurate. This compound is formed by treating thionyl chloride with alcohol in the presence of pyridine, but commences to decompose at 18° C. and cannot be distilled.—**Paul Jodot**: The diffusion of silica during the formation of Corsican jaspers.—**Conrad Kilian**: The age of the Harlania grits, and the extension of the Silurian in the eastern Sahara.—**Couvreur**: Comparison of the testa of lamellibranchs and gastropods.—**Louis Dangeard**: The presence of coccolith and coccosphere beds in the laguno-lacustral Oligocene of Limagne.—**H. Colin** and **P. Billon**: Potash in the sugar beet.—**Émile Saillard**: Sugar beets and molasses (nitrogen and raffinose).—**L. Bordas**: The comparative anatomy of the ovaries of some Hymenoptera.—**Charles Pérez**: The successive replacement of the visceral sacs in *Chlorogaster*.—**Jules Amar**: Vital capacity and pulmonary ventilation.—**Léon Binet** and **M. V. Strumza**: The hæmatopoietic power of carotene. In anæmic dogs the administration of carotene by the digestive tract has a marked influence in increasing the proportion of hæmoglobin.—**Jean Saidman, Jean Meyer**, and **Roger Cahen**: The local effects in the rat due to electric fields of very high frequency. Regional irradiation causes a relatively slight rise in the general temperature, but causes a sharp rise in the temperature of the irradiated region. Abdominal irradiation produces death when the temperature reaches 43·5° C.—**Boris Ephrussi**: The factors limiting the increase of cultures of tissues *in vitro*. Meaning of the residual energy.—**Delherm** and **Laquerrière**: A new electrotherapeutic apparatus for the production of long period alternating waves and undulatory currents.—**C. Levaditi, A. Vaisman, Mlles. R. Schoen** and **Y. Manin**: The calcifying action of bismuth.

LENINGRAD.

Academy of Sciences (*Comptes rendus*, No. 26, 1930).—**E. Voronovskaja**: The transformation of a series of functions by the differences of its terms.—**K. Nikolskii**: The geometry of the Dirac equation.—**G. Laemmlein**: The regular formation of twins in porphyro-quartz of Samshvildo. The author believes that the orientation of the composite parts of a twin is not accidental but occurs according to some definite laws of crystallisation.—**L. Kamanin** and **V. Slokevitch**: A discovery of *Spaniodontella* strata and of deposits of the first Mediterranean stratum in the Nikopol area of manganese deposits.

Comptes rendus, No. 27.—**V. Chlopin** and **A. Ratner**: The distribution of a dissolved substance between the crystalline and the fluid phase. An experimental study of the distribution of radium between crystals of lead nitrate and their solution at 0° and at 25°. The distribution occurs strictly according to the Berthelot-Nernst law.—**N. Gutkova**: A new titanosilicate, the murmanite of the Lovozero tundras. Physico-chemical, optical, and crystallographical characteristics of the mineral are given.—**M. Korsakova** and **E. Nikitina**: The influence of the associated bacteria on the nitrogen régime of *Granulobacter pectinovorum*. When *Granulobacter* is associated with various ærobic bacteria, the latter not only create the anærobic conditions required by *Granulobacter*, but also alter the conditions of its nutrition by providing it with the necessary organic nitrogenous compounds.—**M. P. Korsakova**: The mechanism of the reduction of nitrates (3). A species of bacterium, not identified exactly, was found by the author to be able to reduce nitrates, but the reduction does not reach the stage of free nitrogen.—**T. Ščegoleva-Barovskaja**: New Mordellidæ (Coleoptera) in the collections of the Zoological Museum of the Academy of Sciences. Descriptions of *Mordella fallaciosa* and *M. curvipalpis*, spp. nn., from Turkestan, *Mordellistena similis*, sp. n., from European Russia, and *Silaria antennalis*, sp. n., from Yakutsk province.

SYDNEY.

Linnean Society of New South Wales, June 24.—**C. Deane**: Trichopterygidæ of Australia and adjacent islands. Descriptions of twenty new species of this family under ten genera, five of which are new.—**J. W. Evans**: Notes on the biology and morphology of the Eurymelinæ (Cicadelloidea, Homoptera). The Eurymelinæ are found principally on Eucalyptus trees, the eggs being laid in incisions made by the females in the bark of these trees. There are five nymphal instars, the nymphs being gregarious, as are the adults of many species. Both nymphs and adults are attended by ants; the latter feed on the 'honey-dew' or excreta of their charges. In spite of the ubiquity of their food-plants, their distribution is localised, due to the control effected by their many parasites and predators.—**F. A. Craft**: The physiography of the Shoalhaven River valley. (2) Nerrimunga Creek. Nerrimunga Creek and its tributaries drain an area of tableland to the west of the Shoalhaven River, into which they flow. The western divide between the Wollondilly and Shoalhaven waters is a level ridge varied in places by monadnocks. This falls to an extensive plain of the order of 2000 feet above sea-level, across which the streams flow in shallow valleys. Tertiary deposits are found extensively on this surface, and towards the east of the area stream channels filled with Tertiary drift are found down to 300 feet below the plain, which has been partly dissected by the deep gorges of Nerrimunga Creek and the Shoalhaven River.—(3) Bulee Ridge. Bulee Ridge, to the east of the Shoalhaven River at the head of the coastal fall, consists of horizontal sandstones, and rises from 2000 feet above the Shoalhaven south of Tallong to 2600 feet in its highest portion. On the west it falls away to the Shoalhaven Plain at 2000 feet, but the western slopes have been considerably dissected. The ridge is of considerable age, and protects the tableland from the destructive erosion of the coastal slopes.—**E. Le G. Troughton**: Three new bats, of the genera *Pteropus*, *Nyctimene*, and *Chearephon*, from Melanesia. The genus *Pteropus* is recorded for the first time from Ongtong Java, Lord Howe's Group. The range of the genus *Nyctimene*, not hitherto recorded southward of Guadalcanar in the Solomons, is extended some 350 miles to the Santa Cruz Group, while the third species, an insectivorous bat of the wrinkle-lipped genus *Chaerephon*, from the island of Ysabel, records the first known occurrence of the family Molossidæ in the Solomons.

An International Congress of Prehistory.

SCIENCE unquestionably is greatly indebted to France for the part she played in the efforts to re-establish relations between the scientific workers of different countries after the War. Anthropologists, in particular, should be grateful to their French colleagues for the initiative which led to the foundation of the Institut International d'Anthropologie (even though the Institut failed to attain internationality) and the organisation through that body of a congress of anthropology and prehistoric archæology at Liège, which was the first post-War common meeting-ground for some, though not all, of the anthropologists of different nationalities who had been kept apart for so many years by stress of circumstance. Yet curiously enough, France has failed to carry matters to their logical conclusion. Notwithstanding the admission of countries formerly enemy to participation in the later congresses which have followed that at Liège, the international status of these meetings has been called seriously into question, while in its organisation the Institut, which has made itself responsible for these assemblies and virtually has retained supreme control, is, for practical purposes, predominantly of one nationality.

The efforts of anthropologists outside France to ensure that these congresses in future should be truly, and not merely nominally, international in status and composition, has led to a counter-movement which was referred to in the leading article of NATURE of Mar. 1, 1930. This is manifest in the revival, ostensible rather than real, of the Congrès International d'Anthropologie et Archéologie Préhistoriques, which met last at Geneva in 1912. In theory it sat in joint session with the Institut at Lisbon in 1930. Long before that meeting, it was made evident that this measure would not satisfy everybody. It was, therefore, decided at the meeting to appoint a small committee consisting of nine members, to consider and report to an adjourned meeting in Paris in September 1931 on the future relations of the old Congrès and the Institut. This report will be presented on Sept. 20 next, the day on which the recently announced Congress in connexion with the Colonial Exhibition will open. In that report, a majority of the surviving members will recommend that the Congrès International d'Anthropologie et Archéologie Préhistoriques should be resuscitated, but entirely apart from the Institut and as a free and independent, migratory body, functioning "selon ses anciens statuts". The terms of the report have been known for some time; but the Institut shows no sign that it will acquiesce.

In the meantime, the informal conference of representative archæologists of various nationalities, summoned on the personal invitation of Dr. Bosch-Gimpera, of Barcelona, has met at Bern. This conference, it will be remembered, follows up a movement initiated at the International Archæological Congress held at Barcelona in 1929. It met on May 28 last. The British archæologists present, Prof. J. L. Myres and Prof. V. Gordon Childe, were charged with messages from the Royal Anthropological Institute and its Joint Committee for Research and Teaching urging the re-establishment of the old Congrès and pressing for a wide general scope in future congresses.

The significance of the latter recommendation lies in the fact that there is a strong and growing body of opinion on the Continent in favour of broadening, and at the same time defining, the archæological side of the future congress, so as to take in the whole group of related studies bearing on the problems comprised in what is now known as prehistory, while limiting its scope in other branches of anthropology to their bearing upon prehistory. As there is no congress in existence which covers anthropological studies broadly, the Royal Anthropological Institute naturally desired that advantage be taken of the opportunity to bring together students in all branches of the subject.

A report of the proceedings at Bern on May 28, by Prof. J. L. Myres, appears in *Man* for July. Although the invitations were issued to archæologists individually, the meeting may be regarded as fairly representative from the point of view of nationality. Archæologists from fourteen European countries were present. The conference sat under the chairmanship of Dr. Bosch-Gimpera.

It is clear from Prof. Myres's report that, although alternative proposals were carefully considered, there was an overwhelming majority in favour of following a certain course. A strong preference was shown for a specifically prehistoric congress rather than any general combination of prehistory with anthropology or ethnology. It is clear also that there was a very strong desire for a quite fresh congress without any connexion with previous organisations. The suggestion of the Royal Anthropological Institute that the old Congrès should be revived as an independent body was put to the vote; but the resolution found three supporters only. Thereupon, on the motion of M. Lantier, of the Musée des Antiquités Nationales, St. Germain-en-Laye, it was unanimously resolved to establish a new Congrès International des Sciences Préhistoriques et Protohistoriques. This congress will include all the studies which contribute to prehistory—geology, palæontology of animals and plants, anthropology, ethnology, folk-lore, archæology, etc., in their application to prehistory and protohistory.

Statutes for the new congress were drafted and adopted on the spot. On general lines they resemble those of the old Congrès. It will meet once in every four years, and each meeting, before adjourning, will fix the date and place of the next meeting and elect a president and general secretaries for that occasion. In certain respects the new organisation differs from the old. The following provision, which will give a certain permanence and stability lacking in the older organisation, is especially worthy of note:—The congress will be managed by a permanent council consisting of one or two members for each country, chosen in the first instance by the Bern meeting. These may be assisted by one or two secretaries. Vacancies hereafter will be filled by the congress on the nomination of the council. In any country which invites the congress, these members, with their secretary or secretaries, will act as the nucleus of the organising local committee, this local executive being confirmed and completed by the congress when it meets. Obviously this organisation opens up unlimited possibilities in the way of securing agreement and continuity in an international policy in archæology. Sir Charles Peers and Prof. Myres have been appointed members of the council for Great Britain, with Prof. Gordon Childe and Mr. C. F. Hawkes, of the British Museum, as secretaries. Finally, to ensure continuity with the old Congrès, surviving members of its permanent council have been invited to act as an honorary committee with other distinguished persons and, eventually, all retired members of the permanent council.

The British representatives had been authorised by the Society of Antiquaries of London and the Royal Anthropological Institute, in the event of it being decided to resuscitate the Congrès International d'Anthropologie et Archéologie Préhistoriques, to proffer an invitation for the congress to meet in London in 1932. In view of the event, this invitation could not be tendered. It has since been decided that the invitation should hold good, and the Royal Anthropological Institute and the Society of Antiquaries of London, with the support of the Joint Committee for Anthropological Research and Teaching, the Royal Archæological Institute and other learned societies, have invited the new congress to meet in London at the end of July 1932.

This cannot be regarded as the most happy ending of a protracted and tiresome series of negotiations extending over some years. The best that can be said for it is that the result, however deplorable, is inevitable. The French Institut has shown itself unwilling, or as it declares, unable under French law, to enlarge its management so as to become truly international. Nor has it shown itself ready to offer as a solution a dignified withdrawal from an impossible situation by a voluntary surrender of control of the congress and co-operation with others in reviving the old Congrès as an entirely independent organisation. The situation now created cannot endure; but, as a result, prehistorians must, for a time at any rate, submit to the imposition of two congresses, with the resulting dissipation of energy and division of interests. On the other hand, as general anthropology and ethnology are left without a congress of their own to cover the rest of these subjects on inclusive lines, the suggestion of another independent organisation has been favourably received—a further burden on an already overburdened world.

Agriculture and Physics.

The Physical Properties of the Soil. By Dr. Bernard A. Keen. (The Rothamsted Monographs on Agricultural Science.) Pp. vii + 380 + 2 plates. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1931.) 21*s.* net.

STOKES'S paper on the theories of the internal friction of fluids in motion was published in 1845, and in it he discussed the motion of a sphere falling through a viscous liquid and arrived at a well-known equation. That result has become the basis of important experimental results in widely differing branches of physics: for example, in Wilson's cloud expansion apparatus for the determination of the electronic charge or in Millikan's researches in the same subject, or again as a viscometer, while towards the end of the last century it was applied to estimate the size of the particles in a sample of soil. How this is done is explained in detail in the earlier pages of the book under review, and the account is both interesting and instructive.

The physics of the soil is a comparatively new subject, complex to an alarming extent, and yet, as the book shows, of great importance. Results of marked value have already been reached by workers in the field, who, had they done nothing else, and this is far from being the case, have deserved our gratitude by directing attention to the complex nature of the subject and the field it opens for fruitful investigation. As a simple example of this complexity, take the effect of water on the heat conductivity of soil.

The conductivity of dry soil is about one-third to one-half that of water; hence the addition of water should increase its value. This was found to be the case, but as the soil is moistened its conductivity rises much beyond that of water. As the amount of water is increased, the conductivity falls again to about that of water.

The soil is composed of grains of material which in a solid form have a conductivity much in excess of that of water. When water is added to the dry grains of sand, it fills the narrow interstices and by its surface tension draws the grains closer together, increasing the area of contact of grain to grain, and where they are not in contact, replacing air by water. Thus in the damp mass there is a substance more nearly representing the solid form of the material, with a conductivity above that of water. As the water content is increased, the grains move apart; the water becomes the medium through which the heat passes. The apparent paradox is solved by an elementary application of physical principles. And so it is with a number of other more complicated problems. The book gives an admirable account of the application of physics to many of very real importance to the agriculturist and indicates one direction in which science can aid agriculture; a few examples may be given.

Soil differs from one part of the country to another and on the nature of its constituents depends its fertility; the grains of which it is composed vary in size, and a first step in the examination of any soil is its mechanical analysis, the determination of the sizes of the particles of which it is composed, for on these its characteristics largely depend. This analysis aims at dividing the soil into a series of groups of particles, each within some prearranged limits of size, and determining, by weighing, the percentage weight of each group. It is here that Stokes's law comes in; separation by sieves is possible when dealing with the larger particles, but the smaller grains are far too small for this. After the largest particles are removed, the remainder is mixed with water and allowed to settle; the larger particles fall more quickly; after settling for a specified time—the time in which a sphere of a given radius r_1 takes to fall from the top to the bottom of the beaker of liquid—the turbid liquid is poured off; it contains no particle of larger radius than r_1; the sediment is treated in a similar way, and thus, by varying the height and time of settling, the soil is divided into as many fractions as are required. Each of these is then weighed.

This is a long and tedious process; the result is best represented by drawing a summation curve, in which the abscissæ represent the radius of the particles, and the ordinates the percentage of particles having a radius equal to or less than the corresponding abscissa.*

Now this percentage can be obtained more rapidly by mixing the soil and water as above, allowing it to settle for a specified time t, taking a sample of known volume of the liquid mixture at a depth x, and determining the weight of its solid contents as a percentage of the whole weight. For at the time t, all the particles at a less distance from the top than x which have a velocity as great or greater than x/t, will have passed below the level at which the sample is taken; it will contain no particles of a size greater than that corresponding to this velocity, while smaller particles will be distributed in the same proportion as in the soil originally. A series of such samples enables a complete mechanical analysis to be made. The book gives a detailed account of the method, with a discussion of the errors to which it is liable, and the accuracy attainable.

Or to take another illustration: the motion of water in the soil is clearly of the utmost importance to plant life. What are the laws which regulate this? And what knowledge can physics give of these laws?

In the first attempts to answer this question the soil was treated as a bundle of capillary tubes in which the water rose and fell in accordance with the pressure changes and the ordinary laws of surface tension; another attempt was based on the supposed analogy between the flow of water in a porous space and the conduction of heat or electricity. Briggs in 1897 abandoned the capillary tube hypothesis, and, taking the porous space as an assemblage of cellular spaces, worked out the moisture distribution on the principle that the surface energy of the films distributed over the particles of soil tends to become a minimum. It was not realised until later that the shape and volume of the spaces between the grains rather than the surfaces of the grains themselves were the essential factors of the problem, and a chapter in the book gives a most interesting account of Haines's work at Rothamsted, both theoretical and experimental. He deals, as had been done earlier by Schlicter, with an ideal soil, a large number of small equal spheres, examining the shape and volume of the interstitial spaces which correspond to different modes of packing, and the air and water distribution within this cellular structure for different moisture contents. At first the water is distributed in discrete rings round each point of contact—this was called by Versluys the pendular stage; later the rings come into contact; the water is continuous throughout the volume but air still occupies some of the spaces; finally the air is entirely expelled, the spaces are filled with water, and the capillary stage begins. Experiments by Haines and others have verified this in a remarkable way, and while, of course, soil is not the ideal medium of the theory, there is no doubt that it does represent the processes actually in operation.

Or again, a primary object in cultivation is to secure a good tilth, and for this purpose the soil is broken up into finely divided particles by various implements, of which the plough is the most important. This leads naturally to the question: What are the forces required for disintegration and how does the soil respond to the action of these forces? A further question, discussed later, is: What should be the form of plough which will disintegrate the soil most satisfactorily? Now the finer particles of soil are mostly clay, and clay when wetted forms a plastic mass. Thus we have a discussion of the motion and changes of shape of a plastic mass under pressure and the modifications in Poiseuille's equation for the motion of a viscous liquid to fit it to represent the motion of a cylinder of plastic material forced along a tube. Four stages are recognised: at first there is no motion, as the pressure increases the paste moves forward as a rigid plug, then we find a central portion moving as a rigid body surrounded by a cylindrical shell in stream-line motion, and finally the composite motion is replaced by stream-line throughout. From this we pass on to the behaviour of these fine clay particles as the moisture content of the soil is increased, the properties of soil and clay suspensions, leading to problems of colloid physics; to the agriculturist the properties of clay particles of most interest are those concerned in the coagulation of a suspension, because the surface forces concerned in this probably operate in field conditions in connexion with the formation of compound particles, and thus we find in the book much valuable information as to theories of the mechanism of coagulation.

A most interesting chapter discusses the physical properties of soil under cultivation, and the application to practice of some of the principles considered in previous pages.

---

* The abscissa might be the velocity acquired by a particle of radius r in falling, or the logarithm of either of these quantities.

An important question for the farmer is what power does he require to plough a field, and the ingenious dynamometer designed for this purpose is fully described. But experiments at Rothamsted in this connexion have led to one or two important results. A whole field may to the eye or to any other cursory examination appear of uniform character; a dynamometer test may, however, show over its surface marked variation in its resistance to the plough: the dynamometer records for various plots of a field of six acres selected for its apparently uniform character indicated variation on the dynamometer scale between 1150 and 1500, and these variations remain over a number of years.

Or again, what should be the form of ploughshare which will do its work with a minimum expenditure of energy? This has been discussed by W. R. Bousfield, among others, in a paper which was read before the Institution of Mechanical Engineers in 1880. One of the earliest to solve the problem was Thos. Jefferson, the third president of the United States.

Consider a plough cutting a furrow in a field in which the unploughed portion lies to the left of the ploughman. His object is to cut a continuous rectangular sod or ribbon from the ground and turn it over so that it may lie with the side uppermost which was originally below and at some suitable angle against the ridge of the furrow on his right. The working surfaces of the plough consist of the coulter and the ploughshare; the former of these is a vertical knife which cuts the left edge of the sod, the front edge of the ploughshare is a horizontal knife at the same depth as the bottom of the coulter; this cuts the under surface of the sod; as the plough proceeds, the sod thus produced moves up the mould board, the continuation of the ploughshare which is formed so as to rotate it, at first about its bottom right-hand corner until it has turned through 90°, and then about the point which was the top right-hand corner but has now become the bottom until, after turning through a further 40° or so, the sod passes off the end of the mould board and comes to rest against the preceding ridge.

From considerations such as these Bousfield developed the fundamental form of the mould board and discussed modifications required by practice.

In the United States, White found that the standard form of mould board used was either a portion of a hyperboloid of one sheet, or was composed of portions of two such surfaces.

Concluding chapters of this most interesting book, covering the history of the subject from ancient days to the present time, deal with meteorological questions, the temperature of the soil and the conduction of heat, the atmosphere of the soil, and the gases it contains; according to figures obtained in Sweden, there is, at a temperature of 15° C., an estimated production of from 7·5 to 10 litres of carbon dioxide per square metre per day.

Dr. Keen is to be congratulated on having written a book of very real value; few persons have any idea either of what has been achieved by the labours of a few interested workers with a knowledge of physics and the conviction that by careful application that knowledge could be used to solve some of the difficulties of the farmer, or of the opportunities which remain—and they are many—to gain from a study of the physical properties of the soil new knowledge which may help man in his struggle to make two blades of grass grow where there was one before.

R. T. G.

Vocational Guidance.

Methods of Choosing a Career: a Description of an Experiment in Vocational Guidance conducted on Twelve Hundred London Elementary School Children. By F. M. Earle, and other members of the staff of the National Institute of Industrial Psychology. Edited with a Preface by Charles S. Myers. Pp. 334. (London: Chapman and Hall, Ltd., 1931.) 12*s.* 6*d.* net.

THE volume just issued by the National Institute of Industrial Psychology provides an account of the most extensive investigation carried out hitherto in the field of vocational guidance. Nearly ten years ago the Institute, in collaboration with the Industrial Health Research Board, carried out a preliminary research on a limited scale—the first of its kind in Great Britain. The experiment was too small to be conclusive, and was intended only as a preparatory trial. The data, however, were sufficient to indicate that the methods proposed were feasible and that the results were likely to be of value both theoretically and practically. As a consequence, with the generous aid of the Carnegie United Kingdom Trust, the Institute undertook a large co-operative inquiry in a number of elementary schools under the London County Council. Six hundred boys and girls were examined by a small band of psychologists. On the basis of the results, advice was given to each of the children, indicating what kind of employment was most suited to their capacities; and their subsequent history was closely traced during a period of three or four years. Another 600 were taken as a control group. These were left to seek employment in the usual way, but were carefully followed up like the others. The primary object of the experiment was to compare the after-careers in the two cases.

The first section of the book describes in detail the procedure adopted. In their final form, the psychological methods employed show a great advance on those usually followed in making a vocational study of an individual child. The inquiries into home circumstances, physical condition, mental state (including intelligence, temperament, character, and predominating interests) are all fully discussed. Occupations and trade processes are classified; and the psychological requirements of each are analysed in detail. Together with the sample tests and record-forms printed in the appendix, the whole review furnishes a workable and scientific scheme of case-study.

The second section of the book describes the inquiry into the after-careers, and draws a detailed statistical comparison between the control group and the experimental group. Here the outstanding difficulty was the extreme complexity of the general problem. So many factors influence a child's actual choice of employment, so many conditions affect his subsequent industrial success, that it might seem at first sight an impossible task to compare two groups in this way. The analysis of the data, however, is masterly; and the final results form a striking confirmation of the value of scientific guidance. Where the boys and girls examined have been able to find occupations either identical with or similar to those originally recommended, there, it appears, they tend to keep their posts longer, their work more frequently gives satisfaction to those who employ them, and they themselves are more contented with their own situation and prospects. To some extent this happens even when the recommendations are based on the rough and ready procedure of the ordinary school conference. But the tabulated figures leave little doubt that when the advice is reached by a searching, scientific study of the needs of the individual child, then the results are far more satisfactory.

It is a high testimony to the Institute's team of investigators, and above all to Mr. Earle, who, as former head of its vocational section, has been mainly responsible for the work, that such an elaborate piece of co-operate research should be brought to so successful a termination. Dr. C. S. Myers, who, as head of the Institute, planned the general lines of the investigation and made the initial arrangements, contributes a preface and a lucid summary of the whole experiment. He puts the final conclusion in these terms: " despite unexpected difficulties, the experiment here under review does demonstrate the ability to predict vocational success in school children ".

The volume itself ends with brief practical suggestions on the organisation of vocational guidance in schools. As Viscount D'Abernon remarks in his foreword, " the day cannot be far distant when in every type of school some such scheme as that adumbrated by the writers will be established, to the lasting benefit of the individual and of the community ". For all such attempts at vocational guidance in the near future, the work carried out by Mr. Earle and his colleagues will form an invaluable model and guide.

German Glaciation.

Das Eiszeitalter: Grundlinien einer Geologie des Diluviums. Von Dr. Paul Woldstedt. Pp. xv + 406. (Stuttgart: Ferdinand Enke, 1929.) 29 gold marks.

DR. PAUL WOHLSTEDT of the Prussian Geological Survey is one of the leading authorities on German glacial geology, and in this concisely written volume he has compressed an account of the nature of glacial evidence and processes, a description of the glacial deposits in various countries, an account of the human remains associated with the glacial drifts, a discussion of the cause of former glaciations, and a long bibliography.

In his preliminary account of glacial phenomena Dr. Wohlstedt describes the various drifts and structures. Regarding the kar or corrie he gives no positive opinion as to its formation, but attributes it mainly to the action of frost. He distinguishes moraines from pseudo-moraines. Kames and osar he regards as both aqueous deposits, osar as banks laid down in narrow channels in the ice, and kames as broader sheets formed by the water that has spread over the country outside the ice. He does not mention the later British literature on these formations. He refers to the varied opinions as to the nature of drumlins, and quotes Fairchild's conclusion that they are due to the combined influence of ice, of the nature of the drift, of the local topography, and of weathering. Dr. Wohlstedt gives an excellent account of stone-polygons illustrated by those of Spitsbergen. He belongs to the school that attributes to glaciers enormous powers of excavation and regards them as the cause of fiords, which he limits to glaciated coasts. He recognises the similarity of some mountain lakes to them, and calls the Walensee a typical fiord. In the chapter on fossil man he remarks that the age of the Taungs skull is uncertain.

The most valuable section of the book is the account of the north German glacial deposits, and its digest of the extensive literature upon them will be especially useful to students in other countries. The author describes the successive concentric ridges of glacial drifts formed along the edge of the Baltic ice in its successive invasions of the north German plain. Some of those ridges are not what would be expected from their identification as moraines. Some of them are unquestionably morainic and consist of typical morainic drift; but others are wide sheets of sand, with complex false bedding, no glaciated pebbles or boulders; but hundreds of stones that have been sand-cut into dreikanters. These deposits, as near Salzwedel, show none of the ordinary evidence of glacial action, and, though they are included on the small-scale maps in the moraines, they are recognised as beds of sand deposited by streams and wind outside the ice sheet. They are fluvioglacial and subaerial sands.

The international correlation of the drifts adopted by Dr. Wohlstedt is based on the German succession. He adopts four glaciations, with perhaps an earlier one of which the evidence is indefinite and is represented in England by the 'Weiburn' Crag. He correlates the four with the Penck-Bruckner Alpine series. His classification is perhaps forced and artificial. It assigns the main British glaciation to the Riss, with the Mindel doubtfully separated from it, and represented by the Norfolk Arctic Bed. The section on the British glacial deposits is probably the poorest in the book. The evidence is mainly collected from the compilations and not from the primary memoirs. The bibliography does not mention Goodchild, Carvell Lewis, J. Smith, Bailey, or Boswell. The chapters on the glaciation of Scandinavia and Finland and of North America are valuable summaries of the evidence for those countries; some other parts of the world receive brief notice.

The author's adoption of a fourfold correlation of the drifts in America and Europe forces him to attribute glaciations to a world-wide extra-terrestrial cause, which he connects with some variation in the sun. But he recognises that solar changes do not alone explain the facts: he considers that glaciations are due to a combination of variable factors, and that, though the initial cause may be astronomical, they are the product of a complex cycle of meteorological influences. He discusses the wandering of the poles and Koppen's conclusion that during the Pleistocene glaciation the north pole was in Greenland; he rejects that view from the evidence of the extensions of the glaciers in South America, which he regards as proving that the poles were at the time in their present positions. He concludes that the problem of former glaciations is still unsolved.

Short Reviews.

Problems and Methods of Research in Protozoölogy. Contributors: Justin Andrews, M. A. Barber, H. P. Barret, E. R. Becker, G. H. Boyd, Chas. F. Craig, Frank G. Haughwout, Robert Hegner, M. J. Hogue, Francis O. Holmes, T. S. Hsiung, John F. Kessel, Harold Kirby, Jr., Charles A. Kofoid, W. H. W. Komp, R. R. Kudo, M. S. MacDougall, Reginald D. Manwell, Maynard M. Metcalf, Herbert Ratcliffe, Lowell J. Reed, C. W. Rees, Bruce D. Reynolds, Nannie M. Smith, Lucy G. Taliaferro, W. H. Taliaferro, D. H. Wenrich. Edited by Prof. Robert Hegner and Justin Andrews. Pp. ix + 532. (New York: The Macmillan Co., 1930.) 21*s.* net.

THIS volume, to which twenty-seven American workers in protozoology contribute, was designed with the laudable objects of familiarising both students and specialists with recent developments in various fields of protozoological research and of propounding fresh problems and new methods of attack. It consists of 42 chapters, of which 14 are written by the joint editors, Profs. Hegner and Andrews, of the department of protozoology at Johns Hopkins University. They cover a wide range of subjects, and are obviously written not so much to display accepted facts as to stimulate speculative interest in the economics of protozoa and their host-parasite relationships. We have, for example, chapters on the protozoa of termites that apparently assist their hosts to digest a diet of cellulose, on methods of cultivating *Amœbæ* and flagellates, on the flagellates of the latex in Euphorbiaceæ and their insect vectors, on the development of serological methods for diagnosis and classification, and on recent advances in the study of malaria in man and birds, the latter now being freely used as test objects for chemotherapeutic experiment. Throughout the work attention is directed to lines of work that might yield results of interest. The chapter on experimental malaria in birds, for example, ends with a tabulated list of no fewer than 76 questions to which investigators are invited to apply their minds.

A bibliography of text-books and monographs on protozoology, a list of journals in which papers on protozoology appear, and a list of some 800 references to original literature conclude the volume.

Elektroneninterferenzen. Herausgegeben von Prof. Dr. P. Debye. (Leipziger Vorträge, 1930.) Pp. vii + 85. (Leipzig: S. Hirzel, 1930.) 6 gold marks.

This important little book consists of seven lectures delivered at Leipzig during the summer of 1930. The first, by E. Rupp, treats of the internal potential and electrical conductivity of crystals, as manifested in the reflection of slow electrons from metallic and non-metallic crystals in such experiments as those of Davisson and Germer, Farnsworth and Rupp himself. The second lecture, by R. Wierl, describes experiments by himself and H. Mark on interference rings obtained by passing hard cathode rays through vapours like carbon tetrachloride, cyclopentane, and benzene. The third lecture, by H. Mark, discusses these experiments in the light of de Broglie's wave mechanics and Bethe's dispersion theory of electron diffraction. This is followed by a very brief discourse by N. F. Mott on the atom form-factor.

The latter half of the book is devoted to electrons in metals, and begins with a lecture by E. Grüneisen on the relation between the electrical and thermal resistances of metals and the temperature, in which he discusses recent experimental results in the light of the theories of F. Bloch and R. Peierls. The sixth lecture, by F. Bloch, deals with the interaction between the electrons in a metal, and the last, by R. Peierls, with the behaviour of metallic conductors in strong magnetic fields.

The book will no doubt prove very useful to students desiring an authoritative summary of recent experimental and theoretical researches in the fields of electron diffraction and metallic conduction, as well as to research workers seeking material for further investigations.

The Properties of Matter. By W. H. Spikes. Pp. vii + 152. (London: Sidgwick and Jackson, Ltd., 1930.) 4*s*.

Among the multiplicity of physics text-books to meet all types of students and all standards of examinations, there is little which falls under the heading of 'Properties of Matter', other than those of a fairly detailed or advanced type. In the past, a fair part of the subject matter has unfortunately fallen largely between the secondary school and the university. A work which aims at presenting a short and concise course is therefore to be welcomed, and the little book under review is stated by its author to have been drawn up to meet the needs of sixth forms in secondary schools.

A treatment under the conventional headings, in the space of some 140 pages of fairly large type, has necessarily involved considerable condensation, but the author's object appears to have been satisfactorily carried out. Emphasis is laid on the historical development, and the exposition is clear and attractive. A minimum of the simplest calculus is employed. The addition of a short section on dimensions of quantities and its illustration in the results deduced would seem desirable. On page 15, the invention of the astronomical telescope is incorrectly attributed to Kepler. A selection of test questions is appended. N. M. Bligh.

Le littoral du nord de la France et son évolution morphologique, suivi d'un appendice ; L'Évolution du rivage du nord de la France et l'activité de l'homme. Par Abel Briquet. Pp. v + 439 + 45. (Paris: Armand Colin, 1930.) 60 francs.

In making a detailed study of the changes in the coastline of Picardy and Flanders, the author has produced a valuable study in physical geography. His region extends from about the estuary of the Somme to Flanders, and so includes two areas of coastal plain and the intermediate high coastline around Calais and Boulogne. The study is very detailed, and discusses at length the processes involved, and thus may be used to throw light on coastal changes in general. Particular attention is paid to the evolution of the estuaries, the formation of dunes, and the evolution of the drainage of the plains. An appendix discusses the problems of human settlement in relation to the physical geography, and brings together various considerations that have been mentioned in the main part of the book. There are many sketch maps and diagrams.

The Works of Aristotle. Translated into English. *Physica.* By R. P. Hardie and R. K. Gaye. Pp. viii + 260. (Oxford: Clarendon Press; London: Oxford University Press, 1930.) 10*s*. 6*d*. net.

The publication of Aristotle's "Physica" is an important addition to this standard translation of his works into English. The book should be popular with men of science and philosophers alike, in so far as it refers particularly to fundamental doctrines concerning motion, space, time, and the different types of cause studied by the physicist. Aristotle's views on these topics are too well-known to be restated here. A careful study of his "Physica" would show, however, that the philosopher of Stagyra has a great deal to say with important bearings on our modified physical concepts. The translation itself, edited by Prof. Ross, satisfies the needs of real scholarship. T. G.

Handbuch der biologischen Arbeitsmethoden. Herausgegeben von Prof. Dr. Emil Abderhalden. Lieferung 331. Abt. 9: *Methoden der Erforschung der Leistungen des tierischen Organismus,* Teil 4, Heft 4 (Schluss). *Methoden und Technik der vergleichenden Stoffwechselphysiologie bei Wirbellosen.* Von H. P. Wolvekamp. Pp. 439-524 + xiv. (Berlin und Wien: Urban und Schwarzenberg, 1930.) 5.50 gold marks.

This small section of Abderhalden's great undertaking deals with the very specialised methods adopted in research into the metabolism of invertebrates. It is of especial interest to zoologists engaged in laboratory work, more particularly since the author has brought his account thoroughly up to date.

Influence of Modern Hydro-Electric Power Development on the British Coal Trade.

By Dr. BRYSSON CUNNINGHAM.

THE striking, and even astonishing, development during recent years of sources of hydraulic power for the generation of electricity, gives rise to a pertinent and interesting inquiry as to the influence this widespread creation of hydro-electric energy is having, and is likely to have, upon the output and use of coal for power production. It is a question of not inconsiderable importance to Great Britain, since exportations of coal represent a very remunerative source of revenue to colliery proprietors and shipowners, while to the country as a whole, coal, as one of its most abundant and valuable mineral deposits, is a factor of the highest importance in its industrial activities.

As regards the internal economy of Great Britain, the available supplies of water power are of minor account: they are too insignificant to affect British coal consumption in any appreciable degree. It is in regard to countries abroad, Canada, Italy, Scandinavia, and Switzerland, for example, where extensive mountainous regions afford abundant scope for the realisation of hydraulic power, that the consideration chiefly applies, and Great Britain is concerned so far as their development affects the quantities of coal which are exported to customers abroad.

The fuel equivalent of one installed horse-power produced by water wheel, or turbine, has been computed by the Canadian Department of the Interior at 5½ tons of coal per annum. This figure is, of course, variable according to conditions of a widely differing character, and it involves several assumptions which are not of universal application, but it affords some idea of relative values and may conveniently and justifiably be used in general terms for a brief review of the subject. As a matter of fact, it is based on the average annual coal consumption per kilowatt-hour of all public utility power plants in the United States. This consumption has ranged, on a gradually decreasing scale, from 3 lb. of coal per kw.h. in 1920 to 1·69 lb. per kw.h. in 1929—the last-named figure being convertible into the 5½ tons of coal per annum adopted by the Canadian Government as its standard of comparison.

In the most recent report of the Dominion Water Power Bureau, dated Jan. 31, 1931, and reviewed in NATURE of April 18, it was pointed out that, on this basis, the then existing water power installation in Canada of 6,125,012 horse-power was capable of effecting a saving of nearly 33¾ million tons of coal per annum. With the marked economies which are continually being realised in coal consumption in fuel power stations, the equivalent unit value indicated in the preceding paragraph is falling, but the saving of nearly 34 million tons of coal annually is no over-statement at the present time and is believed to be a conservative estimate.

This is for Canada only. If thereto be added the corresponding figures for all other countries in which water power development is in active prosecution, the aggregate arrived at will be of considerable magnitude, and if, furthermore, there be taken into account the potential supplies as yet undeveloped, and, in most cases, greatly exceeding the capacity of the installations in actual operation, the grand total will be of dimensions which may well be described as colossal, and even startling. The United States Department of the Interior has recently issued a statistical statement, prepared by the Geological Survey, placing the world total of potential water horse-power at 447,000,000, of which slightly more than 10 per cent is, as yet, actually developed. This estimate is by no means excessive: it is probably too low from lack of sufficient data. Previous articles in NATURE have shown that there is more than forty million horse-power available in Canada and about twice as much in the United States[1], while several European countries have resources estimated at from five to ten million horse-power each.[2]

At first sight, it might appear that such enormous actual and potential savings in fuel consumption for power producing purposes are bound to affect the coal trade very adversely and to bring about a substantial reduction in British coal exports. Yet, strange to say, this is not the case so far, and on investigation it will be found that the matter is not quite so simple a sum in subtraction as it would appear to be.

The figures in the table on p. 398 show the coal consumption in, and British exports of coal to, five leading countries during the past four years, with corresponding pre-War figures for 1913. From this statement it can be seen that, on the whole, there is remarkably little change in the situation as regards solid fuel consumption. Within not undue limits, the consumption of coal in Switzerland, Norway, Sweden, and Canada has remained approximately uniform and fairly equal to that of nearly twenty years ago. Italy, the one exception, has actually increased its coal consumption.

This unlooked-for and apparently incongruous result can be explained on several grounds, not the least valid of which is that, by reason of the natural expansion of the world's industrial activities and the increase in the amenities of civilisation, there is a corresponding augmentation in the demand for power, which affords scope for supply from sources other than fuel without diminishing the demand for the latter. Omitting other considerations, the rate of hydro-electric development in countries of stationary fuel consumption should be a measure of the natural expansion of industry, but owing to economies effected in fuel utilisation and in manufacturing processes and output, this cannot be claimed as a rigorous standard.

In considering the quantities of fuel consumed, notice should not be omitted of the increasing use of oil and natural gas as substitutes for coal. As yet, however, the gross consumption of such alternatives for power-production purposes appears to be of insufficient proportions to affect the main trend of this inquiry. The Report of the Electricity Commissioners for the twelve months ended Mar. 31, 1930, shows that for a total of nearly twelve thousand million units of electricity generated at 568 stations in Great Britain, the quantity of fuel oil used was about 0·3 per cent of that of coal. In other countries the proportions will naturally vary according to circumstances. In the United States, for example, where supplies of oil are plentiful, the percentage of liquid fuel used for generating electricity in public utility power plants during 1929 was nearly ten times as great, that is about 3 per cent. These two representative cases show that the influence of oil fuel is at present reasonably negligible and does not call for further examination.

QUANTITIES OF COAL CONSUMED IN, AND EXPORTS OF BRITISH COAL TO, ITALY, SWITZERLAND, NORWAY, SWEDEN, AND CANADA.

* Estimated. † Includes coke. ‡ Excluding lignite.

Looking now at the British exportations of coal, it can be seen that, notwithstanding the uniformity of coal consumption, these exports have increased in relation to Canada, but have decreased very materially in relation to Norway and Sweden and less heavily in relation to Italy. Here some discrimination of explanation is necessary.

The decrease in coal exports to the last-named three countries is attributable mainly to foreign competition; particularly, in regard to Scandinavia, on the part of Poland, where the costs of production are much less than those of British coalfields, and where the rail haulage rate to the Baltic ports of Danzig and Gdynia is comparatively very cheap and the port and loading charges are on a lower scale than at British ports.[3] As regards Italy, the most formidable competitor of Great Britain is Germany. Before the War, 90 per cent of the coal imported into Italy was British. The percentage has since fallen to 55, while, owing to heavy deliveries of reparation coal, Germany now sends more than four times her pre-War quantity, representing 31 per cent of the total Italian imports of coal to-day.

Excluding the strike year, 1926, the annual coal output of Great Britain has not varied to any serious extent during the last ten years. In 1922, according to the Board of Trade returns, it was 249,606,864 tons; in 1930 it was 247,235,300 tons. The highest year was 1923 with 276,000,560 tons and the lowest, 1928, with 237,471,931 tons. Exports have shown a rather wider range, reaching 79,459,469 tons in 1923 and falling to 50,055,118 tons in 1928, the quantities for most of the years in the period lying between 50 and 60 million tons.[4]

The figures do not prove very much, one way or another. If there has been no progressive or ultimate increase, there has also been no appreciable decline of extended duration. Indeed, it has to be admitted that it is not possible to draw conclusions of a positive character from the official returns, and pending further evidence, the influence of current hydro-electric developments on the British coal industry must remain something of the nature of an interesting and elusive speculation.

Periodic Physico-Chemical Phenomena.

By Dr. ERNEST S. HEDGES.

PERIODIC phenomena of all types have a peculiar fascination to the human mind, possibly because they suggest some of the processes of life. On the largest scale, mechanical periodicity is inherent in the movements of celestial bodies and of the earth, producing secondary periodicities, which we recognise as the yearly seasons, alternating day and night, the ebb and flow of the tides, and in other ways. These time-periodicities in their turn leave their mark on earthly structures which are in the course of formation, producing spatial periodicities, such as the annual rings in the trunks of trees, and probably the bands in many geological deposits. The seismologist and the meteorologist recognise periodicities in earthquakes, in thunderstorms and other climatic conditions, but periodicity is above all familiar to the biologist. To consider the processes of breathing and the heart-beat is sufficient to indicate the fundamental importance of periodic phenomena in biological systems, quite apart from the interest attached to structures having a spatial periodicity. In fact, periodicity both in space and in time has so come to be regarded as a characteristic of the biological sciences that when it is encountered in purely physical systems it almost constitutes a link between the two.

Although, during the last hundred years or so, periodic processes in physico-chemical systems have been reported from time to time, it is only during the last decade that a systematic study of this principle has been made.[1] The results have shown that both temporal and spatial periodicities are at least as frequently encountered in purely inorganic physico-chemical systems as in biological organisms. It is proposed to apply the term 'periodic structures' to banded and other structures showing a spatial periodicity, and to restrict the term 'periodic reactions' to chemical processes in which it can be shown that the reaction velocity varies periodically.

PERIODIC CHEMICAL REACTIONS.

It is not possible within the limits of a short article to review more than a few types of the periodic reactions which have been investigated. One of the most striking is the curious intermittent action of mercury on hydrogen peroxide, which has been the subject of a considerable amount of research by Bredig [2] and several later investigators. When clean mercury is brought into contact with a solution of hydrogen peroxide, the alkalinity of which has been adjusted within certain rather narrow limits, oxygen is evolved at the interface at regular intervals of about one minute, and during the intervals between the pulses of gas the mercury becomes covered with a film of oxide. The simultaneous periodic changes of surface tension are shown by the pulsation of the mercury surface, and anyone who performs the experiment cannot but be struck with the remarkable similarity to the heart-beat. Bredig remarked upon the enormous influence of traces of catalytically active materials on the mercury-hydrogen peroxide pulse, the fact that both in this system and in the cardiac rhythm the pulse is accompanied by electrical disturbances, and also that both the biological system and its inorganic model are characterised by an unusually high temperature coefficient. He also recognised that both phenomena might be conditioned by the periodic formation and rupture of an unstable film.

The dissolution of metals in aqueous solutions of electrolytes has proved a fruitful field for the examination of periodic reactions. At the beginning of the present century, Ostwald [3] described the periodic dissolution of chromium in dilute hydrochloric acid. Certain (irreproducible) specimens of chromium gave rise to a pulsating evolution of hydrogen. The investigation had eventually to be abandoned, but the phenomenon was traced to the presence of some unknown impurity in the metal.

Hedges and Myers [4] recorded automatically and continuously the rate at which hydrogen is evolved in numerous reactions of this type, and observed a periodic rate of dissolution of zinc, iron, aluminium, magnesium, manganese, and sodium in a number of reagents, including acids, alkalis, neutral salt solutions, water, and alcohols, showing that, given the right conditions, the phenomenon is a general one and is not a special property of chromium. The cause of these periodic phenomena has never been completely elucidated, and subsequent research has been directed to the study of the anodic dissolution of metals under the external application of an electric current, where the velocity of dissolution and other factors can be kept under control. The experiments rendered it quite clear, however, that the periods are obtained only in the presence of some foreign substance, which may be present in extremely small amount. In some cases it was evident that the glass reaction vessel was capable of furnishing the required trace of 'catalyst', whilst in others the addition of colloids in so small amount as one part in a million brought about periodicity. Periodic dissolution was also brought about by placing the dissolving metal in contact with a more noble metal, which had previously been 'activated' by heating in a vacuum, by cold-rolling, by bombardment with cathode rays, or by coating with metal by electro-deposition at high current densities. The behaviour of these metallic couples is closely in line with the periodic anodic phenomena described in the next section, and may conceivably be connected with the formation of oxide films. Colloids might act by stabilising such a film, or, since they are known to be strongly adsorbed at metallic surfaces, might form a film which is broken down periodically by the reacting solution.

Small quantities of catalyst poisons (formaldehyde, potassium cyanide, or sodium arsenite) decreased the frequency of the periods greatly, and larger amounts stopped the periods, whilst not appreciably affecting the normal reaction. The periodicity was destroyed by the addition of one part in a million of chloroplatinic acid. The minuteness of the quantities involved rendered the work difficult, but it is in itself characteristic of biological systems.

Lillie [5] has pointed out the analogy between the alternating activity and passivity of iron in 70 per cent nitric acid and the cardiac rhythm. A regular rhythm is obtained when one end of an iron wire is inserted a few millimetres inside a narrow glass tube, then immersing both in the acid. It appears that the rhythm is always associated with a small local region of the enclosed part, in which the reaction between the wire and the acid is continuous, and from this region waves of activation travel rapidly and periodically over the entire specimen. The enclosed region is therefore similar to the nodal or 'pace-making' region of the heart. The transmission of a wave of activation along a passive iron wire is the nearest analogy we have to transmission along a nerve, and in both instances there follows a temporary non-transmissive or refractory period. Lillie considers that the properties of surface films are involved in both cases. In the passive iron system the spread of the wave of activation is marked by the breakdown and subsequent reinstation of the protective oxide film, which is the cause of the passivity, and in biological systems surface films are believed to underlie the response of irritable tissues to irritation.

PERIODIC PHENOMENA IN ELECTROLYSIS.

Studies of periodic phenomena at electrodes during electrolysis have established the conditions for periodicity at anodes of copper and silver,[6] magnesium, zinc, cadmium, mercury, tin, lead, and an unattackable electrode,[7] iron, cobalt, nickel, and aluminium.[8] Reactions at the cathode [9] have also been studied, and several examples of the periodic electro-deposition of metals through secondary reaction have been observed.

This electrochemical periodicity is manifested by periodic changes of considerable magnitude in electrode potential and in current density, generally accompanied by visible periodic changes at the electrode, such as the intermittent evolution of gas or the formation of a film. The investigations have made it possible to formulate the conditions necessary to secure periodic effects at the anode :

(1) A film must form over the anode.

(2) The film must be soluble in the electrolyte when the circuit is broken. It follows that the electrode may exist in one of two possible states—with or without the film.

(3) The current density must be between two well-defined limits, which depend on the temperature, concentration, and nature of the solution. Periodic phenomena can be realised by so arranging the current density that the electrode has almost equal chances of remaining in one state or passing into the other. The result is that the electrode oscillates continuously between the two states. The region over which this periodic effect can be observed is often very narrow, but is sometimes quite extensive.

In order further to elucidate the mechanism, experiments have been carried out using a rotating anode.[10] The system examined was the anodic dissolution of copper in hydrochloric acid, during which a visible film forms periodically over the anode. The principal results obtained were as follows : (1) At a rotating anode the frequency of the periods is independent of the current density over a wide range ; the frequency is not dependent, therefore, on the rate at which metal ions leave the electrode. (2) The 'characteristic frequency', which is independent of current density, increases linearly with the speed of rotation. Variation of the speed of rotation can produce two effects : (*a*) The anodic product is washed away more quickly ; (*b*) chlorine ions are supplied to the anode at a greater rate. If the frequency were determined by the first of these effects, it would no longer be independent of the current density ; consequently, it may be inferred that the frequency is controlled by the rate of supply of chlorine ions to the anode. (3) The conclusion is supported by the fact that at constant speed of rotation the frequency is directly proportional to the concentration of hydrochloric acid.

The experiments showing that the frequency depends entirely on the rate of accumulation of chlorine ions appear to leave no escape from the conclusion that dissolution of the film does not occur until a certain critical concentration is reached, but that when reaction occurs in each 'pulse' it is complete. This is analogous to the 'all-or-nothing' law so familiar in physiology, according to which a system does not respond to a stimulus until this reaches a threshold value, but the response is complete when that value is reached.

Physiologists explain the periodicity of breathing in a similar way ; respiration occurs every time the carbon dioxide content (hydrogen-ion concentration) of the blood reaches a threshold value.

Experiments on the periodic electro-deposition of metals through secondary reaction afford strong support for the critical concentration view, and are difficult to explain in any other way. For example, in the electrolysis of potassium mercuricyanide solutions, under certain conditions the potassium liberated at the mercury cathode reacts alternately with water molecules and with the complex $Hg(CN)_4''$ ions or undissociated salt, the final effect being a periodic evolution of hydrogen alternating with deposition of mercury. The supposition here is that reaction of potassium with the complex ions does not take place until the ions reach a certain critical concentration by diffusion, and in the meantime reaction with water molecules occurs. The mechanism is similar in outline to the older idea that the heart-beat is caused by alternate reaction with or adsorption of calcium and potassium ions, although that view does not appear to be greatly favoured by present-day physiologists. It may also be pointed out that in colloid systems critical concentrations of ions are required for coagulation, and such systems appear to be particularly favourable for periodic phenomena.

Independent evidence of the existence of such critical concentrations has been obtained by the progressive addition of hydrochloric acid to copper rendered passive by anodic polarisation in hydrochloric acid, and to iron rendered passive by concentrated nitric acid.

PERIODIC STRUCTURES.

The study of periodic structures dates from 1896, when Liesegang [11] made the original observation that silver chromate is precipitated in the form of concentric rings when a concentrated solution of silver nitrate is allowed to diffuse into a gelatin gel containing dilute potassium chromate. Although numerous explanations have been advanced since that time, and in spite of the vast amount of experimental work which has been performed, it cannot be said that the phenomenon is completely understood. The principal fact which emerges from the work of the past thirty years is that periodic precipitation is a very general phenomenon, and it is probable that, given the proper conditions, periodic structures can be obtained from any pair of salts which interact to give a precipitate.

Natural periodic structures resembling the Liesegang phenomenon in appearance are frequently encountered in both geology and biology, but whilst there is evidence to show that banded geological specimens, such as agates, can be traced to the diffusion of salts in silicic acid and other gels, and can thus be correlated with the formation of artificial periodic structures, it is not always safe to apply these principles to the biological specimens. This is partly because of the number of external periodic conditions which might account for their formation, such as alternating day and night, winter and summer, sleep and activity, and intermittent feeding. Typical examples are the form of starch grains and such layered concretions as gall-stones and urinary calculi. Attempts have also been made to apply the Liesegang principle to the markings on butterflies' wings and on the shells of certain molluscs.

Experiments by the author[12] have shown that the formation of periodic structures of this type can be separated into two stages: (*a*) chemical reaction without precipitation, and (*b*) precipitation by coagulation. The periodicity occurs in the second stage of the process. Similar periodic structures were obtained by the simple coagulation of colloidal solutions in gels and in glass capillary tubes. In some of the experiments in coagulation in capillary tubes the coagulum took the form of a spiral or uniplanar wavy fibre, showing an analogy with many natural colloidal fibres, such as wool. The formation of periodic structure was brought down to its simplest conditions, however, by causing concentrated hydrochloric acid to diffuse into glass capillary tubes containing sodium chloride solution, whereupon the sodium chloride was salted out in bands. The experiment eliminates both chemical reaction and colloidal phenomena, and is contrary to some of the best known theories of the formation of periodic structures.

It is concluded from this work that both in the formation of periodic structures and in the production of periodic reactions the essential condition for periodicity is the existence of some *critical condition* determining a change of state which proceeds to completion once the critical value is reached.

Obituary.

Prof. W. E. Dixon, O.B.E., F.R.S.

THE death of Prof W. E. Dixon at his home near Cambridge on Aug. 16 is a loss which scientific medicine in general and pharmacology in particular can ill afford to bear. He was one of the few pharmacologists in Great Britain, and under his guidance the Cambridge School of Pharmacology made considerable progress.

Walter Ernest Dixon was the son of Robert B. Dixon, of Darlington, where he was born in 1871. He was educated at Dulwich and St. Thomas's Hospital, London, and, after holding the posts of house physician and demonstrator of physiology, he was elected professor of pharmacology at King's College, London. He went to Cambridge in 1902 as assistant to the Downing professor of medicine; he was appointed University lecturer in pharmacology in 1909 and reader in this subject and assessor to the regius professor of physic ten years later. During the War, his special knowledge was placed at the disposal of his country, and for this he was created O.B.E.

Dixon's reputation as a pharmacologist was international, and he was consulted frequently by important bodies with regard to those subjects of which he possessed a peculiar and intimate knowledge. He had been a member of several Government committees, more recently those on ethyl-lead petrol and drug addiction. He was a member of the League of Nations committee on drugs of addiction, and only a few weeks before his death he visited Geneva in this connexion. In particular, the British Medical Association, the Pharmaceutical Society, and the Society of Apothecaries will deplore his passing, for he had played an important part in the work and administration of these bodies.

In his laboratory Dixon was indefatigable; he was responsible for the University teaching in pharmacology at Cambridge, while in addition to supervising research work, he himself performed a great number of experiments. His literary output was considerable; he once told the writer that he had contributed to every important British medical periodical except one. He had written upon a large number of pharmacological and physiological subjects, the most important, perhaps, being his work, in conjunction with the late T. G. Brodie, upon the nature of asthma. His book, "A Manual of Pharmacology", first published in 1907, is a standard work upon the subject, and many pages of the British Pharmaceutical Codex came from his pen. He was joint editor of the *Journal of Pharmacology and Experimental Therapeutics*, and, in addition, he was on the editorial committee of several other publications.

Many honours came Dixon's way. He was elected a fellow of the Royal Society in 1911 and a fellow of the Royal College of Physicians in 1930. During his visit to Canada last year, the University of Manitoba conferred upon him the degree of LL.D. He had been president of the Section of

Pharmacology and Therapeutics of the Royal Society of Medicine, and, in 1929, he was president of Section I (Physiology) at the Cape Town meeting of the British Association.

Dixon possessed the faculty of explaining the most difficult problem in the simplest possible way. He was a fluent and ready speaker, and was often requested to lecture upon both scientific and semi-popular subjects. His addresses upon "Tobacco" and the "Cocktail Habit" are examples of his powers in this direction.

It is impossible to enumerate all Dixon's interests and activities. He possessed a buoyant, kindly nature; he was always cheerful, always full of life and energy. He had a host of friends, and it has been remarked, with truth, that he never said an unkind word. The day before his death, he was, as usual, in his laboratory planning future work and apparently in normal health, while those with whom he was in daily contact little thought that this was the last occasion upon which they would enjoy his confidence. He died, as he would have wished, in harness; and pharmacology has sustained its greatest loss since the death of Schmiedeberg. F. B. P.

Prof. J. W. Hinchley.

John William Hinchley was born at Grantham in 1871, but at an early age was resident in Lincoln, and was a pupil at the Grammar School. He obtained valuable experience as an engineer with Ruston, Proctor and Co. and with the Reliance Ironworks at Lincoln. In 1893, Hinchley gained a National Scholarship and became a student at the Royal College of Science and Royal School of Mines, South Kensington. Here his career was brilliant, and he obtained a Whitworth Exhibition (1894) and later a Whitworth Scholarship (1896), but he did not avail himself of this. Whilst a student, those keen interests, which he maintained throughout his life, in all that would help his fellows were evidenced by his activities in the Students' Union, on the committee of the old students' rooms—indeed a dreary place compared with the premises of to-day—and the debating society.

Hinchley took a first class Associateship of the Royal School of Mines, and after a short time as junior demonstrator went to Dublin, where he was engaged under Prof. Joly in perfecting Joly's three-colour photographic process. Here Hinchley gained very valuable mechanical experience in working out the intricate details of ruling the colour screens used. Returning to London, he was for a time with the late Mr. Oscar Guttmann. This was followed by a residence of some years in Bangkok as technical head of the newly established Siamese Mint. This period abroad, in a climate which did not suit him, undermined his health for some time.

On his return to England, Hinchley took up consulting work, and about this time developed his ideas of the association of the chemist and engineer in the individual as a 'chemical engineer', an association which has been much criticised, but which has won through, thanks largely to Hinchley. He was mainly instrumental in the formation of the Chemical Engineering Group of the Society of Chemical Industry and was its first chairman, and also in the formation of the Institution of Chemical Engineers, from the inception of which he was honorary secretary. Hinchley first lectured at the Battersea Polytechnic and later at the Imperial College of Science and Technology, where he was appointed as the first professor of chemical engineering.

On his return to South Kensington, Hinchley at once threw himself into the social life of the College, and was particularly interested in the new Students' Union, with its many amenities. He also took a very active part in the affairs of the Old Students' Association.

Hinchley became a freemason whilst in Siam and took a great interest in masonry on his return. He was largely instrumental in the formation of the Imperial-College Lodge, of which he was a past-master, and took an active part in the formation of the Radium Lodge.

As a teacher of chemical engineering, Hinchley had exceptional qualifications by reason of his very practical engineering experience, combined with an extensive knowledge of chemistry and mathematics. Not only had he the requisite qualifications, but he also had the gift of getting the best out of his students. As Prof. H. E. Armstrong wrote in an appreciation in the *Times*, "he treated the subject with a common sense, a breadth of outlook, and in a practical way which made his pupils of altogether special value in industry".

All those who were privileged to know Hinchley intimately will always remember him as one whose greatest pleasure was to be doing something for others. It was the key-note of his life. Give him some project to organise which would be helpful to others and he never spared himself. His many friends were deeply distressed by the several weeks of suffering which he patiently endured before the end in the Freemasons' Hospital on August 13.

J. S. S. B.

Group-Capt. Martin Flack, C.B.E.

To Martin Flack, whose death at the age of forty-nine years occurred on Aug. 16, we are indebted for the clear setting out during the War of those principles which made high flying possible by the use of oxygen breathing apparatus, and for the tests which differentiated suitable from unsuitable candidates for flying. Moreover, he did excellent work in recommending the physical training required to make and keep those chosen for the air service in fit condition. In addition, at the time when cerebro-spinal fever caused great anxiety, he did first-class work in elucidating the means, by ventilation, spacing out beds, etc., of keeping down infection and for carrying out serum treatment.

Flack raised himself by his native genius and sterling character from the elementary school to the University of Oxford, and kept himself by scholarships up to the taking of his medical degrees. Then, beginning research with Sir Arthur Keith, he discovered anatomically the sinu-auricular node, and was first to prove by experiments on the living heart that this is the pace-maker of the heart—a most notable discovery. Next, working with me as demonstrator of physiology at the London Hospital Medical School, he proved himself to be a splendid teacher, and was enthusiastic in showing to his class experiments which the student usually has no opportunity of seeing, such as those fundamental ones by which Harvey proved the circulation of the blood.

Flack and I together carried out researches on the influence of breathing excess of carbon dioxide and deficiency of oxygen, and on the increased power to do work which the breathing of oxygen gave. We showed that runners, boxers, and swimmers were improved in performance by breathing oxygen.

This work enabled Flack, when the need suddenly arose, to design the means for overcoming the failure of war-pilots to fly at high altitudes. Oxygen breathing apparatus was supplied and perfected so that flying became possible at extreme heights. Flack tested himself in a chamber at a pressure equal to a height of well over 40,000 feet—a very courageous performance. He also contrived the tests for pilots who had crashed, which showed whether their nervous system had become stable or was still unfit for flying. One of these tests was the ability to hold the breath long and the effect of this on the blood pressure, another the power to raise a column of mercury 40 mm. high and hold it by the breath as long as possible. He was able to classify pilots as good or bad, without knowing their records for crashing, and his classification agreed with the records. By the tests which Flack introduced, the efficiency of the air service was very greatly increased, and for this Great Britain owes him a great debt of gratitude.

Flack was troubled by a rheumatic heart, but, in spite of this, was a most cheery, humorous, and energetic man, and no one could be a better colleague than he. His far too early death will be lamented by many friends, and by the Air Service in particular. LEONARD HILL.

MR. DAVID DAVIES.

BY the death, on Aug 15, of David Davies, of Gilfach Goch, Wales has lost one of her most industrious students, and the science of palæobotany an interesting personality.

Born near Merthyr Tydfil, sixty-one years ago, Davies began his working life as a 'door boy' in a local colliery, and as soon as he was old enough became a collier. He had a passion for knowledge, especially that relating to the rocks among which he worked, and took advantage of the evening class facilities then available in the Rhondda Valley, with the result that, after passing through the various grades of colliery official, he became, while still a comparatively young man, agent to the Britannic group of collieries of the Cambrian Combine.

The interest in fossil plants that, in his boyhood days, gained for him the nickname "Dafydd Ffossil", was maintained as he grew to manhood, and, encouraged by well-known palæobotanists, he began to collect systematically from each of the separate horizons at which fossil plants occurred in the eastern part of Glamorgan. His object was to record not merely the kinds of plants that were present, but also the associations of plants and the relative abundance of each species, genus, and class of plants, and thus to lay the foundations of an ecological study of the successive 'coal-forests' that occupied the site of the South Wales coalfield.

The results of Davies's work have been published in the *Quarterly Journal of the Geological Society*, the *Transactions of the Royal Society*, and other journals, and at the time of his death, which occurred suddenly while on holiday in Norway, he was nearing the completion of a series of parallel investigations in the more westerly regions of the coalfield. During the course of such intensive collecting, he got together a very large series of coal-measure fossils, the majority of which he presented to the National Museum of Wales for the use of future students: the remainder passed into the hands of the late Dr. Kidston, and are now in the collections of the Geological Survey.

It is a matter for regret that Davies did not live to complete the work upon which he had been engaged for nearly forty years, but his manuscripts have been so carefully arranged that the essential parts of his conclusions can still be published; and the 'David Davies' collection in the National Museum of Wales, probably the largest collection from any one coalfield in the world, is a permanent memorial to his industry and devotion to science. Some years ago his work was recognised by the University of Wales and the degree of M.Sc. conferred upon Davies, and he has served for a long period upon the Council and upon the Court of Governors of the National Museum of Wales.

David Davies did not allow his interest in science to interfere with the discharge of his official duties, and he had the satisfaction of seeing a colliery district that was threatening to become derelict when he assumed charge, in 1911, enter upon a new phase of activity, resulting in the growth of Gilfach Goch from a village of some two thousand inhabitants to a community five times as large.

F. J. N.

DR. W. E. DOWNEY.

BY the death of W. E. Downey, as a result of an accident on Aug. 19 while climbing the Jungfrau, the Research Laboratories of the G.E.C. lose a brilliant worker of outstanding promise; the staff of the Laboratories lose a colleague of unusually charming personality.

Downey entered the Wembley Laboratories five years ago, and his first task was the extremely difficult one of investigating the manufacture of carbon black, with a view to putting it on a more rational basis. To this he brought a combination of scientific ability and technical insight which enabled him to apply scientific principles, so far as that can be done, to what is inevitably a very empirical process. Later, he had an opportunity of applying the same qualities to other problems, and showed at once that real talent for industrial research which depends on an ability to inspire other and less experienced workers and also to collaborate with colleagues engaged in other branches of work.

Downey, who was only thirty-one years of age, was educated at Huddersfield College and the Imperial College of Science and Technology. At the latter he had a distinguished career, culminating in the award of a Beit fellowship. During this period he published some papers on chemiluminescent oxidations; his death, coming when it did, robbed him of an opportunity of producing further work of a more fundamental kind which he would undoubtedly have originated.

Mr. J. Adamson, honorary secretary of the Institute of Marine Engineers since its foundation in 1889, on August 20, aged eighty-one years.

Dr. G. Bryce, president of the Royal Society of Canada in 1909 and one of the founders of the University of Manitoba, where in 1891 he was appointed head of the Department of Science and lecturer in biology and geology, aged eighty-seven years.

Mr. C. R. Hewitt, librarian of the Wellcome Historical Library and formerly assistant librarian of the Royal Society of Medicine, on Aug. 15, aged sixty-one years.

Lieut.-Col. J. R. Lord, C.B.E., medical superintendent of the Horton (County of London) Mental Hospital, Epsom, who was past president of the Royal Medico-Psychological Association and editor of the *Journal of Mental Science*, on Aug. 10, aged fifty-seven years.

News and Views.

For several centuries quinine has held its place as a specific in the treatment of malaria, but although it controls the disease it does not have a permanent curative action. Within the last few years, a quinoline derivative called 'plasmoquine' has been introduced to therapeutics as a substitute for quinine: investigation of its action suggests, however, that its value is rather complementary to the latter. Quinine attacks the asexual stages of the malarial organisms, except the sporozoites, but has little action on the sexual stage: plasmoquinine attacks the gametocytes. In the prevention of malaria, attention has been directed chiefly to the prevention of breeding by the mosquitoes in which the sexual stages of the developmental cycle of the malarial organisms take place, and to the prophylactic administration of small doses of quinine. The prevalence of the disease in the countries where it is endemic bears witness to the difficulty of eradicating it, although thorough destruction of all breeding-places is effective. A simpler method, available where the latter is impracticable, would therefore be of very great value.

Col. S. P. James, W. D. Nicol, and P. G. Shute describe some recent experiments on the prevention of malarial infection in human beings by the ingestion of plasmoquine, in a recent issue of the *Lancet* (vol. 2, p. 341; 1931). Ten volunteers were infected by allowing half a dozen mosquitoes (*Anopheles maculipennis*), infected with the parasite of benign tertian malaria, to bite the forearm; 0·02 gm. plasmoquine was taken three times daily after food for six days, the first two doses being taken before infection. The controls were patients who were to undergo a course of malariotherapy. The result was that the controls developed their first febrile paroxysms about a fortnight after infection, whilst none of the volunteers showed at any time any sign of the disease for the next four weeks. Plasmoquine therefore prevents mosquito-borne infection in healthy individuals when given in prophylactic doses, presumably by completely destroying the sporozoites; quinine does not have this property. It appears probable that a valuable preventive agent is now available: the results of its trial in a population among which malaria is endemic will be awaited with interest.

It has become platitudinous to talk of the educational possibilities of broadcasting. Everyone knows that the possibilities are there; but how many realise the machinery which the British Broadcasting Corporation has assembled in order that those possibilities may be realised? That machinery, sensitive to new impulses, and subject always to any alterations which will bring better results, ought to be better known. Briefly, two councils are responsible for what are vaguely known as 'talks': the Central Council for Broadcast Adult Education and the Central Council for School Broadcasting. For our present purpose we refer only to the former, but each council is composed of every kind of educational interest, and is divided into committees to which special tasks are assigned. For example, the Programmes and Publications Sub-Committee meets very frequently and deals with the important, difficult, and delicate task of planning talks and securing speakers who are not only expert in their subjects but who can speak in language of common currency.

A new pamphlet, which may be obtained from the B.B.C., shows how all this work is being developed. It presents, under the title of "The Changing World", the plan of talks from September 1931 to March 1932. We would emphasise the word *plan*. 'Talks' have never been confined to mere haphazard observations on topical subjects, and the present programme shows a series planned in advance for a special purpose. They involve greater continuity between courses on given subjects, and unity of theme and treatment.

The general titles are significant: the modern dilemma, industry and trade, literature and art, science, the modern state, education and leisure. All the speakers will be attempting to answer certain questions: What have been the forces of change which have affected the present century? What has been the influence on social thought and circumstances? *What is the significance to the future of these changes, and what responsibility rests with us to remodel our ways of life?* We italicise the last question deliberately; for, if a series of talks can help us to give a scientific answer to them, the process of broadcasting will have shown its supreme educational value, in the fullest sense of the phrase.

RESOLUTIONS passed at the second International Discussion Conference, held at Geneva on July 1–4 by the International Management Institute and attended by delegates from nineteen countries, afford some reply to certain criticisms of rationalisation, particularly those which suggest it is responsible for over-production, unemployment, the mechanisation of work, increased economic instability, and the imposition of handicaps on weaker businesses and countries. The exceptional depression in world business is attributed less to economic factors than to political and social disorder, especially unsatisfactory international relations. While technical rationalisation results in the production of larger quantities of goods at lower prices, remedy is not to be found in the retardation or restriction of this process but in the extension of the principles of rationalisation to the technique, organisation, and administration of industry, first on a national and then on an international basis, and in the more efficient organisation of distribution. Subject to adequate publicity to safeguard the interests of consumers, the considered establishment of voluntary agreements to eliminate over-production and irrational competition is recommended, and a scientific study of distribution problems, based on international information. The Conference considered that among the many causes of unemployment, rationalisation was economically justifiable, being productive and carrying its own remedy in improvements in production and economy of human effort. The importance of minimising the displacement, assisting the displaced workers during the transition period, and of co-operation between employers' and workers' organisations was emphasised.

THE elimination of exhausting and objectionable tasks, the improved hygienic conditions, and improvement in prospects of promotion, wages, and hours of work are among compensations which rationalisation can offer for the alleged increased mechanisation of work, and the Conference recommended further efforts to encourage the full utilisation and development of the capacity of the individuals. Mistaken judgment in rationalisation has contributed at times to economic instability, and the Conference urges the importance of the development of professional institutions on wider industrial lines, so as to provide all the basic facts essential to direction and reorganisation, and the practical extension of rationalisation principles to whole nations as well as to industry. The professional organisation thus visualised will assist in the insurance of the weaker members of national or international groups against excessive risk. The importance of a close study of the social consequences of rationalisation measures is reiterated, rationalisation being both a tool and a method, and consequently capable of abuse as well as rightful use. A vigorous development of management research group movements is indicated, and closer co-operation between industry and education.

A PROJECT of some interest to scientific workers is the proposal for the formation of an international bibliography of translations, which has been favoured by various international writers', publishers', and librarians' organisations, as well as by the Institute of Intellectual Co-operation. A sub-committee of the Committee on Intellectual Co-operation of the League of Nations, reporting in July on the project, considered that a publication of this type would render valuable service in art, literature, and science, facilitate the rational collection of information for writers, publishers, translators, etc., and prove a starting point for other endeavours to co-ordinate and systematise translation. The plenary committee was requested to take action with the view of securing the early publication of an international bibliography. Co-ordination of scientific bibliography is still a problem of fundamental importance, and the committee of scientific advisers in its July meeting considered the ways in which the obstacles to this and other problems of scientific co-ordination could be more effectively overcome. Scientific co-ordination has both a technical and a moral aspect, in so far as it not only improves the conditions of scientific work but promotes intellectual *rapprochement* and international understanding. Probably the most effective contributions in this field will be made by efficient national organisations and by international associations the chief task of which is the organisation of scientific work. The Committee on Intellectual Co-operation has, however, assisted in the creation of an atmosphere favourable to such developments.

A LARGE and interesting power station which utilises peat for fuel is operating at a distance of 75 miles from Moscow. It is called the Shatura power station, and is situated near three small lakes lying close together, and adjoins an immense peat bog. The present operations cover about fifty square miles. There are three large boiler-houses fitted with chain grate stokers specially adapted for burning peat. The turf is supplied in two forms, sods and dust, the dust dropping on the top of the sods in the furnace. The latest boiler put in is made to burn turf dust only; it has a number of oil burners to heat up the furnace before commencing, but has no chain grate. The present way of collecting the turf is by means of powerful hydraulic hose jets which play on the turf and wash it down into an excavated pit as a wet sludge. It is pumped out of this on to the fields, where it is left to dry. Then a slicer on a caterpillar tractor runs over the field, cutting the turf into sods and turning it over. A year's turf has to be collected and dried in four or five months. It is stated in an article by F. C. Wigham in the *Electrical Times* of Aug. 13 that other work must be found in the winter for the 5000 men employed on the turf field. The turf work is a separate business from the electric works and sells its product to the latter at a profit. All industries in Russia must now earn 6 per cent on the capital employed. In the annual report, it is stated that 920,000 tons of turf were consumed last year, the cost of the turf in the bunkers being a little more than 11 roubles per ton, the par value of the rouble being 2*s*. 1*d*. and its purchasing value being about half as much. The power is transmitted to Moscow at 115,000 volts, and the cost per unit last year was 2·20 kopeks, a kopek being equal to ¼*d*. In every five days, half the head staff are away on holiday on one day and the other half on another day.

IN connexion with the Weir report on railway electrification, it is of interest to notice that the electrification of the G.I.P. railway between Bombay, Poona, and Igatpuri has revolutionised passenger and goods traffic and has been of immediate benefit to Bombay and its neighbourhood. It seems probable that considerable main line electrification will be undertaken in North and South India in the near future. The electrified section of the railway extends for 272 track miles. The total amount of the original estimate was about four million pounds, and Messrs. Merz and McLellan, of Westminster, were the consulting engineers. The power supply for the main line system is obtained from a steam power station, and coal of a lower grade than that utilised by the steam locomotive is used for the boilers. The transmission system consists of two high-pressure transmission lines extending 272 miles and supported on lattice type steel towers, of which there are about 2000, their average height being 70 feet. There are 840 miles of steel-core aluminium conductors used in the transmission. The distance between consecutive traction substations on the main line is twelve miles. The pressure of transmission is 95 kilovolts, and this is transformed into 560 volts at the open-air substations and then converted into 1500 volts direct current by rotary machines connected in series. Only five of the substations have attendants, the remaining substations being controlled from the former by electrical methods. The goods locomotives for the line were made by Messrs. Metropolitan Vickers Electric Co., and each weighs 120 tons, being the largest hitherto built in England. Smooth running has been obtained with speeds up to 80 miles per hour, and the scheduled time from Bombay to Poona has been reduced by 30 per cent. The whole scheme has been carried through in three years with practically no interruption of the normal traffic.

THE British Drug Houses, Ltd., London, N.1, have recently issued various pamphlets describing certain of their products. The catalogue of fine chemicals includes both organic and inorganic compounds, analytical reagents, indicators and standard stains. All the commoner substances are stocked in standard packages of 25 gm., 100 gm., 250 gm., and 500 gm. A leaflet describes an outfit for the simple estimation of the blood area in 0·1 c.c. of blood according to the method of Osman and Close (*Brit. Med. Jour.*, Vol. 1, p. 1064; 1931). The urea is converted to ammonia by adding urease to the blood, and the process completed by precipitating the proteins with trichloroacetic acid, filtering and estimating the nitrogen in the filtrate colorimetrically against a series of standards. For the injection treatment of varicose veins, ampoules of sodium morrhuate (5-10 per cent solution) and of quinine and urethane solution are issued as sclerosing agents. When properly carried out, this treatment results in permanent cure and is much simpler than operative removal. It is well known that the liquid extract of ergot of the British Pharmacopœia contains little or no ergotoxine: moreover, most solutions of the latter deteriorate on keeping. The British Drug Houses are issuing a liquid extract guaranteed to contain, by physiological test, 0·03 per cent ergotoxine, and also, an improved preparation, 'Ergodex', of the same strength, which is miscible, contains the whole alkaloidal content of ergot and exerts the full therapeutic effect of the entire drug. It suffers no loss in activity after storage for 12 months when kept in well-closed containers protected from bright light.

IN recent years our knowledge of the deep living pelagic fauna of the oceans has been greatly advanced through collections made by oceanographical research vessels. It is safe to say, however, that the larger part of the examination of the animals themselves has been undertaken on the preserved material either in museums or in other institutions. Such observations as can be made on the delicate organisms and on the living animals themselves have had to be noted on board ship, where vibration and other movements of the vessel do not make for ideal conditions. To be able to examine living collections on the day they are caught in the peace of a shore laboratory is therefore an ideal to be sought after. This possibility has recently been proved by the Bermuda Oceanographic Expedition of the New York Zoological Society under the leadership of William Beebe, who gives a short account in *Zoologica*, vol. 13, Nos. 1 and 2. The laboratory is established on Nonsuch Island, and with the aid of a tug, the *Gladisfen*, collections can be made in 1000 fathoms of water a little more than five miles from the shore; living material is brought to the laboratory in cooled water. It is hoped that in this way much interesting information otherwise unobtainable will become available.

IN the keeping of aquaria the opinion is current that the successful maintenance of fish and plants can be accomplished only if sunlight falls upon the tank at some part of the day. But the revision of this opinion is suggested by an article in the *Aquarium Review* for July, where the author describes his two years' experience of a community tank without sunlight. The tank in question measures 54 in. by 12 in. by 12 in., holds roughly about 30 gallons of water, and is heated to about 74° F. by a simple arrangement of two fish-tail gas jets playing upon a distributing layer of sheet tin beneath the slate bottom. The room in the window of which the tank is placed faces due north and is situated on the fourth floor of a five-storey building in a London street. The success of the arrangement is shown by the fact that about forty tropical fishes, selected for their bright colouring and peaceable habits, live there in amity, and that by the cutting-off of a portion at the end of the tank by a partition of opaque glass many broods of viviparous fishes have been reared. The study of the article is commended to naturalists who have been deterred by apparently unpromising conditions from installing tropical aquaria.

IN the *Aquarist* for July-August, W. J. Pitt tells of a dwarf chamæleon (*Chamæleo pumilus*) having had two litters without a second impregnation. The reptile was bought in London on April 9 of last year, when it appeared to be pregnant, and—the species being viviparous—duly brought forth a dozen young, all perfect and (except three) living, on April 17. No male was kept with it, but nevertheless on Oct. 23 ten more young were born, but this time dead and, with the exception of two, one of which was perfect and the other nearly so, in an early stage of development. This, as the observer remarks, makes untenable the suggestion that the journey from South Africa had caused the first litter to be prematurely born; it may be added that a litter of twenty-two would be a very unlikely number—about double the normal expectation. It is mentioned that an occurrence like the above is apparently unrecorded for reptiles, though well-known in some viviparous fish, such as the swordtails (*Xiphophorus*), now familiar to aquarists.

THE Annual Report of the Joint Board of Research for Mental Diseases, formed by the City and University of Birmingham, for the year ending March 14, gives an outline of the work of the Laboratory. A general attack on the problems of mental disease is being made from the bacteriological, histological, and chemical points of view. Negative as well as positive results are recorded. Mention is made that a murder-suicide case was examined for nasal sinus disease. Presumably as this is a laboratory report, it represents the more physiological approach; parallel with this there should be a psychological study. Even granted that it could be shown that a suicidal-murderer had some physiological defect, this does not prove that this defect was related as cause and effect to his behaviour.

IN an article by Dr. Ellice McDonald on "Cancer Research and the Scientific Method" (*Science*, July 17, 1931, p. 55), the principal biochemical deviations from the normal in the cancer patient are detailed. These comprise increased glycolytic activity and diminished lactic acid formation of tumour tissues, increased alkalinity of the blood plasma, and diminished calcium and increased potassium content of cancer cells. It is considered, therefore, that any cure for cancer must be capable of altering these conditions and bringing them back to normal. At present these appear to be the only criteria that can be formulated for a cancer cure.

AN exhibition of modern optical instruments has been arranged at the Science Museum, South Kensington, and will remain on view until the end of October. Among the two hundred exhibits are apparatus for spectrophotometry in the ultra-violet, an aerial camera which takes 100 photographs with one filling, a projection microscope magnifying up to 5000 times, rangefinders, theodolites, etc.

ON the evening of Aug. 10, one of the greatest earthquakes of the year occurred in western China (NATURE, Aug. 22, p. 299). Its epicentre has been determined by the U.S. Coast and Geodetic Survey, from a large number of records, as situated in lat. 42° N., long. 90° E. (Science Service, Washington, D.C., Aug. 11). The origin was thus in the Sinkiang province of China, on the west edge of the Gobi desert, an area so sparsely settled and so far from lines of communication that direct news of the earthquake can scarcely reach us for many weeks or months, if ever.

THE Institution of Heating and Ventilating Engineers is appealing to the industry for £2000 in order to construct an experimental room enclosed within a larger structure, so that the outer surfaces of the walls of the room may be exposed to controlled conditions and the efficiencies of different methods of heating the room determined. Promises may be sent to the Institution at 12 Russell Square, W.C.1, and are subject to the decision of the Department of Scientific and Industrial Research to proceed with the scheme.

WE have recently received from the British Museum (Natural History) part 2, fascicle 4, of a monographic work on the Diptera of Patagonia and South Chile, in course of publication. The present contribution deals with the Simuliidæ, by Dr. F. W. Edwards, and the Caratopogonidæ, by Drs. A. Ingram and J. W. S. Macfie. It is well up to the standard of its predecessors, and, when completed, the whole work will form an important addition to our knowledge of the fauna of the region concerned.

THE Imperial Bureau of Plant Genetics for Herbage Plants, which is located at the Agricultural Buildings, Alexandra Road, Aberystwyth, has issued the first number of its *Bulletin*. The numbers are to appear quarterly at 1*s*. 6*d*. per issue, 4*s*. for the present year, and 5*s*. annually thereafter. The first number contains abstracts of current papers on herbage, classified according to the decimal system, and indexed. *Bulletin* No. 3, issued at 3*s*., contains a detailed account, by Prof. R. G. Stapledon, Mr. T. J. Jenkin, and Mr. R. D. Williams, of the methods employed in herbage breeding at the Welsh Plant Breeding Station, Aberystwyth. This is illustrated by three plates, and the methods are explained particularly in connexion with various grasses, including cocksfoot grass, and such leguminous crops as the clovers and lucerne. These methods are of much value in connexion with the production and improvement of pasture grasses and fodder crops.

Letters to the Editor.

The Corpuscular Explanation of Cosmic Rays.

WITH reference to the attempts that are being made to determine whether the cosmic radiations are corpuscular or undulatory in character, such as those described by Bruno Rossi,[1] there is one point which I have vainly tried to understand. Why is it assumed that such rays would or could have the high penetrating power of cosmic rays? As I tried without success to point out at the recent discussion at the Royal Society, there is no experimental evidence of corpuscular rays being able to traverse more than 4 mm. of aluminium. It is, of course, known that a few of the β-rays of radium and thorium have energies, as measured by their magnetic deviability, up to some millions of volts. But what experimental evidence is there that these have greater penetrating power than rays of lower energy? Is it not rather to be expected that it would be less, or do the ordinary conceptions of relativity not apply to the theory of relativity? If we try to get the necessary penetrating power by the increase of mass of the particle due to its speed, is not the mass of every other particle with which it collides similarly increased?

FREDERICK SODDY.

Oxford, Aug. 22, 1931.

Measurements on the Absorption of the Penetrating Corpuscular Rays coming from Inclined Directions.

IN a recent discussion on the cosmic rays,[1] Prof. Geiger has pointed out that it would be of interest to make comparative measurements on the absorption of the penetrating corpuscular rays coming from different inclinations to the vertical.

Such an experiment was performed by me shortly before I read this paper, by measuring the diminution in the number of coincidences when a screen of lead 9 cm. thick was introduced between two Geiger-Müller's tube-counters (5 cm. in diameter and 15 cm. long) placed with their axes horizontally, at a distance of 17 cm.

By inclining more and more to the vertical line the plane containing the axes of the two tube-counters, thus increasing the thickness of the atmosphere in the direction of those rays which can determine the coincidences, I expected to find a progressive hardening of the corpuscular radiation, similar to the one which had been stated, by filtering the radiation through a lead screen.[2]

The experimental result did not confirm this expectation. Indeed, with the two counters placed vertically the one above the other, I measured an absorption of 23·2 ± 1·6 per cent; whilst when the plane of their axes was put at an angle of 60° to the vertical line, the absorption was found to be 32·5 ± 3·5 per cent.

It appears, therefore, that the slant rays are softer and not harder than the vertical ones.

This result may be accounted for by assuming that the corpuscular rays generate in the atmosphere a softer secondary corpuscular radiation, and that the relative amount of the latter is in an inclined direction larger than in the vertical one.

Isotopic Displacement in Hyperfine Structure.

THE analysis of the hyperfine structure of several lines in thallium[1] indicates the existence of two distinct sets of energy levels; one for Tl 203 and the other for Tl 205. Each isotope has a nuclear spin $i=\frac{1}{2}$. For the line $6s\ 7s\ {}^3S_1 \longrightarrow 6s\ 7p\ {}^1P_1$ in Tl II, the doublet width is approximately the same size for the two isotopes, which signifies that the magnetic moments must also be approximately equal. The distance between the centres of gravity of the two doublets, however, is greater for Tl 205. Jackson,[2] studying rubidium, concludes that the lines are displaced toward the ultra-violet for the heavier isotope.

From existing theories of hyperfine structure, one is led to conclude that such a bodily displacement would occur even when both isotopes have zero magnetic moment. Experimental evidence as to this would be valuable.

It appears, then, plausible to assume that the electric field produced by the nucleus is not the same for the two isotopes. Whether the thallium nucleus, with a spin $i=\frac{1}{2}$, can have either a permanent dipole moment or a permanent higher moment is doubtful, if one may make an analogy with the case for the external electronic system.[3] Accordingly, the discussion will be confined to central fields, the difference between the two being in the radial dependence of the potential energy.

In order to determine the order of magnitude of the perturbation on a Schrodinger electron by deviations from the Coulomb law near the nucleus, it is probably sufficient to assume a potential energy curve as follows: $V=V_0$ for $r<r_m$, and $V=-\frac{Ze^2}{r}$ for $r>r_m$, where r_m indicates the radial extent of the nucleus. Since calculation showed that relativistic effects would not influence the result appreciably, the following treatment will not take them into account.

Sommerfeld ("Erganzungsband", p. 75) gives the radial function as $R=\frac{1}{N_r}\rho^l e^{-\rho/2} L_{n+l}^{2l+1}$, where $\rho=\frac{2Zr}{n}$ and $\frac{1}{N_r^2}=\frac{4(n-l-1)!}{n[(n+l)!]^3}$.

Atomic units are employed.

In the range from 0 to r_m, $\rho<<1$ and $e^{-\rho/2}\cong 1$. Consequently the only part of the Laguerre polynomial which makes an appreciable contribution is the constant term.

If w_1 and w_2 are the displacements of a $7s$ energy level, and of a $7p$ energy level respectively, then

$$w_1=\frac{1}{N_r^2}\int_0^{r_m}\left(\frac{Z}{r}+V_0\right)r^2dr[L_7^1(\rho)]^2\cong 2Zr_m^2+\frac{4}{3}V_0r_m^3,$$

$$w_2=\frac{1}{N_r^2}\int_0^{r_m}\left(\frac{Z}{r}+V_0\right)r^2dr[L_8^3(\rho)]^2\cong \frac{1}{3}K^2Zr_m^4+\frac{4}{15}K^2V_0r_m^5$$

where $K=\frac{2Z}{n}$.

The displacement w_1 is much greater than w_2, since electrons with $l>0$ do not approach as close to the nucleus as do the S electrons. Accordingly, in Tl II, the $6s\ 7s\ {}^3S_1$ level should be displaced much more than is the $6s\ 7p\ {}^1P_1$.

Neglecting w_2 then, and letting r_1 and r_2 be the nuclear radii of the two different isotopes, the difference in displacements is $\Delta w = 2Z(r_1^2 - r_2^2)$, if $V_0 = 0$. Experimentally, $\Delta w = 0{\cdot}2$ cm.$^{-1} = 10^{-6}$ atomic units. If we take $r_1 = 10^{-12}$ cm. and $r_2 = 9 \times 10^{-13}$ cm., then we obtain an effect of this order of magnitude. In any event, V_0 could be varied also, so that there seems to be no difficulty in accounting for the order of magnitude of the isotopic displacement on the hypothesis that the deviations from Coulomb's law near the nucleus are responsible.

My thanks are due Dr. Dirac for helpful discussion.

Hyperfine Structure of Thallium II.

THE hyperfine structure of Tl II has been investigated by McLennan [1] and co-workers and partially by Schüler and Keyston.[2] Certain discrepancies in the results of the former authors can be attributed mainly to the low resolving power of the instrument employed (3 metre grating). The absence of characteristic fine structures in the magnetic analyses of the same authors is probably of the same origin.

With the large grating and the Weiss magnet at the Physical Institute at Tübingen, we have investigated the magnetic transitions of the hyperfine energy levels of singly-ionised thallium employing field-strengths of 15,000–43,350 gauss, in a manner similar to that employed by one of us [3] for the principal arc lines of thallium. A typical example of such transitions is the line λ 3092. In this case, the magnetic field disturbs only the ${}^1P_1$ levels (classified as $6s6p\,{}^1P_1 - 6s7s\,{}^1S_0$). The photometer curves, reproduced in Figs. 1 and 2 (magnification 30), made from fifth order plates, show quite clearly the effect of changing fields on the separations. In the perpendicular polarisation, the separation AB increases while CD decreases with increasing field; the sum of the two distances, however, remains practically constant. If the Paschen-Back effect were complete, the separations would be equal. The separation EF in the parallel components decreases with increasing field strength and is not resolvable at 43,350 gauss.

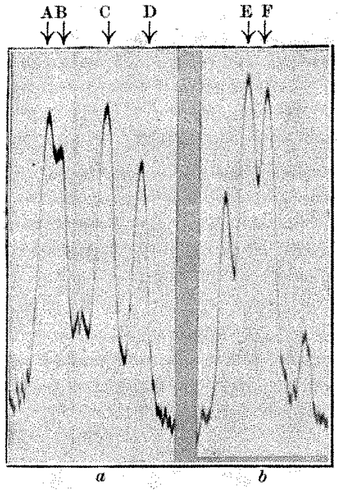

FIG. 1.—*a*, Perpendicular polarisation; *b*, parallel polarisation. H = 14,700 gauss.

The above analysis gives us a value of 0·092 ± 0·002A., or 0·96 ± 0·02 cm.$^{-1}$ for the hyperfine structure of the doublet λ 3092 in a zero field, and shows that the levels of $6s6p\,{}^1P_1$ are inverted.

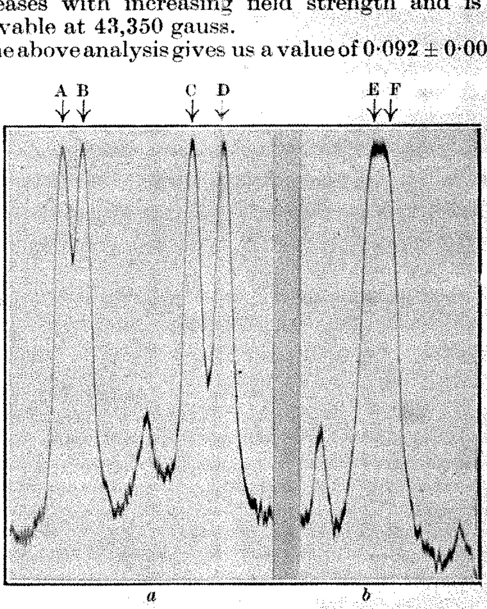

FIG. 2.—*a*, Perpendicular polarisation; *b*, parallel polarisation. $H = 32{,}500$ gauss.

A complete study of the Zeeman analyses of this and other lines of thallium II will be reported elsewhere.

WE have recently published two communications [1] concerning an isotope displacement effect in the hyperfine structure of thallium II. On the other hand, in a recent paper on this subject,[2] J. C. McLennan and M. F. Crawford state that they have discovered no trace of an isotope effect. In order to avoid misunderstanding, we wish to point out that this apparent contradiction is entirely due to the fact that the resolving power of the grating used by McLennan and Crawford is insufficient to separate the lines due to the two isotopes. The smallest separation resolved by McLennan is $\Delta\nu = 0{\cdot}370$ cm.$^{-1}$; the largest isotope displacement is $\Delta\nu = 0{\cdot}280$ cm.$^{-1}$. With a Fabry-Perot étalon we were able to resolve separations of $\Delta\nu = 0{\cdot}040$ cm.$^{-1}$, that is, a tenth of the resolution obtained by McLennan.

When this fact is taken into consideration, the results are in complete agreement. McLennan's revised term analysis shows that the term which he previously denoted as $6s7p\ {}^1P_1$ is really a $1_1{}^0$ term of the complex group $5d^96s^26p$; this correction must therefore be made in the notation of the lines 5490 and 4765 which we investigated. This change is of importance, since it shows that the two large isotope displacements arise from terms of this complex group, whilst the ordinary singlet and triplet terms exhibit smaller displacements.

Evidence for the Spin of the Photon from Light-Scattering.

IN a recent communication (NATURE, **128**, 114, July 18, 1931) Sir C. V. Raman and S. Bhagavantam remark that the reversal of the sign of circularly polarised light in scattering, as observed by Hanle[1] and by Bär,[2] is to be expected from the quantum theoretical law of conservation for angular momentum. As the quantitative theory of the effect was developed some time ago,[3] it may be of interest to note here the principal results, emphasising the fact that the effect can be understood as well on a purely classical basis.

The properties of every Raman transition (whatever the composition of the incident light may be) are determined by an ellipsoid fixed in the molecule, which gives the deformation of the polarisability-ellipsoid, caused by the nuclear motion corresponding to the transition.[4] From this it follows immediately that the state of polarisation of the scattered radiation for circularly polarised incident light is already completely determined by the depolarisation ρ for linearly polarised incident light, defined in the usual way. More especially, if I_r and I_u are the intensities of the reversed and the unreversed part of the scattered light in the *forward* direction, the following relation holds, both in classical and in quantum theory:

$$\frac{I_r}{I_u}=\frac{2\rho}{1-\rho}. \quad . \quad . \quad . \quad . \quad (1)$$

This is analogous to the well-known relation for natural incident light

$$\rho_n=\frac{2\rho}{1+\rho} \quad . \quad . \quad . \quad . \quad (2)$$

which, besides, also remains valid for circularly polarised incident light, when observed in directions *transverse* to the primary ray.

From (1) it follows that we get reversal of the sign of circular polarisation always if $\rho > \frac{1}{3}$. This is always the case for rotational or rotational-vibrational transitions $\left(\rho=\frac{3}{4},\ \frac{I_r}{I_u}=6\right)$; it can be the case, too—contrary to the statement of Raman and Bhagavantam—for purely vibrational transitions, as ρ can vary here from 0 to $\frac{3}{4}$ (loc. cit.[4]); reversal cannot take place for the undisplaced (Rayleigh-) line, its depolarisation ρ remaining necessarily less than $\frac{1}{3}$.

From the point of view of the conservation law it is important to note that in general a molecule can change its angular momentum without changing its spin energy. The scattered light quantum in this case will have the same frequency, but the sign of circular polarisation is changed. In the quantum theory, these changes are described by jumps in the magnetic quantum number m. The selection rules in scattering are for circularly polarised incident radiation: $\Delta m=0$, 1, 2, corresponding respectively to unchanged circular, linear, and reversed circular polarisation. From this consideration it is easily understood that purely vibrational lines can also show the reversal.

It may be remarked that in the usual observations and also in those of Hanle and Bär, owing to the insufficient dispersion available, the purely vibrational line (Q-branch) and the vibration-rotation branches are measured together. Under these conditions, it has been shown[4] that $\rho > \frac{1}{3}$ (1) for all degenerate vibrations, (2) for vibrations connected with a simultaneous increase of some and decrease of other components of the polarisability-tensor (loc. cit.[3, 4]). For the same cases reversal of the circular polarisation has to take place. This is in good agreement with all the observations on CCl_4, $CHCl_3$, C_6H_6, etc.

Recently also the distribution of intensity over the different branches of a line has been calculated by Dr. Teller and myself.[5] As in the theory of classical scattering, the scattering can be divided into a part dependent only upon the sum of the three principal values of the ellipsoid, this part alone contributing to the Q-branch, and the anisotropy scattering. For the latter, for example, the relation of the intensity of the Q-branch to that of the sum of all rotational branches, is found to be 1 : 2 for symmetrical top molecules, while it is 1 : 3 for the rotator (diatomic or linear triatomic molecules).

Group Rotation in Solid Ammonium and Calcium Nitrates.

THE phenomenon of molecular rotation in the solid state first recognised by L. Pauling[1] is, in accord with his prediction, proving of wide occurrence. In many compounds the excitation of rotation about various axes is accompanied by *gradual* changes in such properties as heat capacity, specific volume, and crystal structure. It is probable, however, that certain *polymorphic* transitions, such as, for example, the one in hydrogen chloride at 93·36° K, are also accompanied by changes in the rotation of the molecules. The three *gradual* transitions in solid hydrogen bromide[2] were interpreted by Pauling (loc. cit.) as accompanying stepwise excitation of rotation of an HBr molecule about three axes. On account of the low scattering power of hydrogen, it would be difficult to verify these interpretations by determinations of crystal structures. We have, however, found changes of the above types in ammonium nitrate.

Ammonium nitrate at atmospheric pressure is known to exist in at least five crystalling modifications.[3] The salt shows a small abnormal change in the specific volume starting at about −50° C. X-ray powder diffraction photographs of the solid at −33° C. and at −78° C. are closely similar, as would be expected if rotations of the *ammonium* groups alone are excited between these temperatures.

Most of the transitions in ammonium nitrate show decided hysteresis. Near −16° C., with ascending temperature, the low temperature modification changes to the usual orthorhombic form,[4] which in turn changes to a monoclinic form near 32° C. The structures of these three modifications are complex and are not yet completely elucidated. It is quite probable, however, that the oxygen atoms are in fixed positions in all. Upon further heating, the monoclinic modification inverts rapidly, near 84°, to a tetragonal form. Upon cooling, this tetragonal phase often persists to approximately 50° C. It inverts reversibly near this temperature to the metastable orthorhombic form;[5] on further cooling, in the region of the metastable transition, the stable monoclinic phase is often produced.[6]

We have observed the transition from the tetragonal to the stable monoclinic form in the presence of a small amount of solvent. Cooling at the rate of about 0·5° per minute, the transition was initiated at 76°, and the temperature then rose to 81° C., due to liberation of the heat of transition. Powder photographs of the tetragonal modification at 105° C. indicate that the unit of structure with $a = 5{\cdot}77$ A., $c = 5{\cdot}00$ A., contains two molecules of ammonium nitrate (NH_4NO_3). The observed intensities of interference maxima are best to be explained by a structure with the nitrogen atoms of NH_4^+ groups at 000, $\frac{1}{2}\,\frac{1}{2}\,\frac{1}{2}$, and the nitrogen atoms of NO_3^- groups at $\frac{1}{2}\,0\,\frac{1}{2}$, $0\,\frac{1}{2}\,\frac{1}{2}$, the nitrate groups rotating in (100) and (010) respectively about axes normal to their planes. The separations of the rotating NH_4^+ and NO_3^- groups in the plane of the NO_3^- groups are 3·80 A.

The tetragonal modification inverts near 125° C. to a cubic phase which persists to the melting-point at 169·5° C. This is the most rapid of ammonium nitrate inversions, but even in this case there is an appreciable hysteresis loop between heating and cooling curves. In one experiment, upon heating, the inversion in the dry salt was initiated at 127·15° and ended at 130°; upon cooling, the inversion was initiated at 123·52°, the temperature of the sample rising to 124·35°, and ended at 123°. Powder photographs of this cubic modification at 135° C. and 155° C. indicate that the unit of structure contains one molecule of ammonium nitrate with $a = 4{\cdot}40$ A. (155° C.). Since the lattice is a cubic one, it follows that the oxygen atoms cannot be in fixed positions. The intensities of reflection are best to be explained by a structure with nitrogen atoms at 000 and $\frac{1}{2}\,\frac{1}{2}\,\frac{1}{2}$ and with the centres of the oxygen atoms statistically distributed on a sphere of 1·25 A. radius around one of these points. The separation of the rotating NH_4^+ and NO_3^- groups is 3·79 A. On the basis of such a structure, it is possible to account for the formation of a limited series of solid solutions between ammonium chloride (NH_4Cl) and cubic ammonium nitrate.[7]

It is thus probable that in solid ammonium nitrate above 125°, all the rotational degrees of freedom of both the ammonium and of the nitrate ion are fully excited. Of the three transitions in the solid that are accompanied by changes in molecular rotations, one is *gradual*; another, although of the polymorphic type and previously not considered unusual, is remarkable for the extent and kind of its hysteresis; while the third is a typical rapid *polymorphic* transition.

The results of this work and of our previous study of the *gradual* transition in sodium nitrate[8] indicate that rotation of the nitrate group is often to be found in crystalline nitrates. Published X-ray diffraction data obtained from calcium, barium, strontium, and lead nitrates[9] and nickel nitrate hexammoniate[10] are extremely unsatisfactory. The crystal structures suggested for these various compounds are probably quite incorrect. The symmetry of barium nitrate determined from piezo-electric and unambiguous optical measurements is different from that of the structure described. The structure of nickel nitrate hexammoniate is known to be incompatible with the symmetry indicated by Laue photographs.

It is probable that the nitrate group has spherical symmetry at room temperatures in all of the compounds mentioned immediately above. The structures are probably similar to that of fluorite, the fluorine ions being replaced by rotating nitrate ions, and the calcium ions by the metallic ions or the $Ni(NH_3)_6^{++}$ group, which is not rotating at room temperatures. In calcium nitrate, on the basis of such a structure, the Ca^{++} to NO_3^- distances are about 3·30 A., in close agreement with the calculated value.

The expected transitions in these compounds are now being studied.

Apparent Dissociation Constants of Carbon Dioxide in Sea-water of Different Salt Contents.

IN addition to neutral salts, sea-water contains a small quantity of 'excess base' in the form of bicarbonate and of carbonate, together with free carbonic acid. The ratio of HCO_3' to CO_3'', free CO_2, and consequently hydrogen ion concentration, varies with time and place, dependent upon the intensity of assimilation by plants, of respiration by animals and plants, exchange with the carbon dioxide of the atmosphere, production of calcium carbonate in the skeletons of coccolithophores and animals, and its solution from calcareous sediments. Further, the interrelation between carbon dioxide tension, hydrogen ion concentration, and excess base in saline physiological fluids has been the subject of much research, concerning which there is a considerable and growing literature.

With the object of extending recent researches by one of us (K. B.) concerning the first and second apparent dissociation constants K_1' and K_2' of carbonic acid in sea-water of varying salinity, and of developing suitable analytical methods of estimating 'excess base' (*Alkalinität*) and pH on board research vessels, collaboration was arranged by the International Council for the Exploration of the Sea. With a knowledge of these two constants and the above two variables, one can calculate the carbon dioxide tension, the total carbon dioxide, and the proportion of bicarbonate to carbonate.

Values for K_1' were obtained by shaking sea-water of varying salinity into equilibrium with sufficient carbon dioxide to bring its pH between 5 and 6, as measured by means of a quinhydrone electrode, the free carbon dioxide being obtained from the carbon dioxide tension as measured gasometrically. The variation of K_1' with content of neutral salts was found to follow closely a formula of cubic root type as employed by Bjerrum,

$$pK_1' = 6{\cdot}518 - 0{\cdot}588\sqrt[3]{C}, \qquad t = 18°,$$

where pK_1' is the negative logarithm of K_1' and C is the concentration in terms of normality of all the cations. Since the composition of the salts in ocean-water is almost constant, the cations are in direct proportion to the salinity, from which they were calculated.

The value of K_2' was measured at a pH of about 9, when the free carbon dioxide may be neglected, $HCO_3' + CO_3''$ equals the bound carbon dioxide as found by gas analysis and $HCO_3' + 2\ CO_3''$ equals the carbon dioxide in combination with 'excess base' as found by titration.

The temperature coefficient of K_1, for which the values found by previous workers do not agree closely, remains to be investigated. The results will in due course be published in the *Rapports et Procès-verbaux* of the International Council for the Exploration of the Sea.

Hydrolytic Adsorption of Activated Charcoal.

THERE is a difference of opinion regarding the behaviour of charcoal as a gas electrode in explaining its hydrolytic adsorption (Frumkin, Schilow). It has been suggested alternatively that acidic or basic oxides formed during activation are responsible for such adsorption, and that charcoal is a negative adsorbent possessing a negative charge in water (Schilow). On the gas electrode theory, charcoal should be positively charged and adsorb acids. Negatively charged oxygen charcoal which adsorbs alkali is known. Both positively and negatively charged charcoals are possible. A relationship between the electric charge, as measured electrokinetically, and the hydrolytic adsorption of either acid or alkali has been pointed out, and it was suggested [1] that 'acid' adsorbing activated sugar charcoal would be positively charged. Negatively charged charcoal with hydrogen or weakly basic cations in the mobile sheet of the double layer should adsorb alkali and liberate acid from a neutral chloride solution. This relationship between the sign of the charge and hydrolytic adsorption has been confirmed with charcoal.

In view of the fact that it is recognised (Frumkin) that the gas electrode theory does not apply to the observation of one of us, the results obtained recently (Roychoudhury) are of interest as showing (*a*) that activated charcoals have generally a negative charge but become positive on sustained washing; (*b*) a relationship between the sign of the electric charge and acid or alkali adsorption; (*c*) the primary adsorption of $H^{\cdot}$, OH', Cl', and SO_4'' ions; (*d*) an anomalous effect of the mass of the adsorbent on the adsorption of acids; (*e*) that alkaline extracts can be obtained even from activated sugar charcoal; (*f*) that both cations and anions are possibly formed during activation, their nature and amount depending on the treatment.

Moreover, the facts observed previously (Frumkin, Schilow), that the adsorption of acid is not determined by the activity of hydrogen ions, that both hydrogen and oxygen charcoals adsorb benzoic acid equally, that hydrogen charcoal adsorbs acids, and the part played by the ash constituents, also suggest a limit to the applicability of the gas electrode theory in this instance.

Orientated Deposits of Copper on Bismuth.

WHEN copper is deposited electrolytically from copper sulphate solution on a cleavage surface (0001) of bismuth with extremely low current density, the minute copper crystals show distinct orientations under the microscope (Fig. 1).

The triangular shaped crystals, nearly equilateral, are of light bluish colour and their sides are parallel to the cleavages $(0\bar{2}21)$ on the surface (0001) of bismuth. The parallelogrammatic shaped crystals, dark in colour, have their longer axes parallel to any of the three directions.

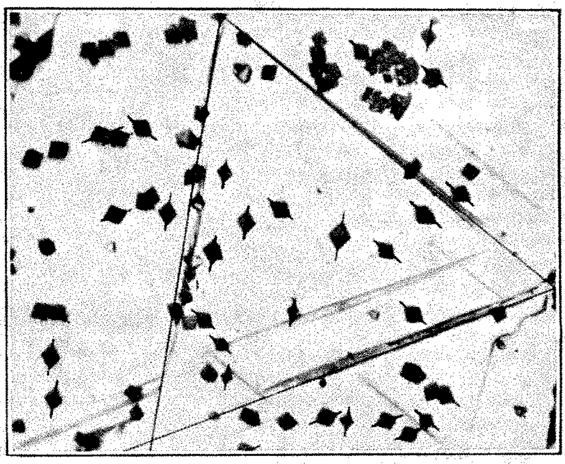

FIG. 1.—Crystals of copper deposited on bismuth. Lines have been drawn marking the long axes of the copper crystals and outlining the bismuth crystal.

The reason for this may be explained by the hypothesis of 'epitaxie' of L. Royer.[1] The details of this investigation will be published in the near future, in the *Memoirs of the Faculty of Engineering*, Hokkaido Imperial University, Japan.

Rotation of 'Dust Devils'.

THE direction of rotation of 'dust devils' has been noted in Lower Egypt and Iraq during the past four years, and the reports received in this office indicate that in about 50 per cent of cases the direction of rotation is clockwise, and in the other 50 per cent anticlockwise. This seems a surprising result, because if a 'dust devil' is due to the raising of dust and sand by the vigorous upward movement of air over a limited area, the rising column should assume an anti-clockwise rotation. I had an opportunity recently of watching the formation of numerous small whirls over a hot sandy space. The whirls did not attain a height of more than 2 ft., and the objects raised were leaves and feathers (not sand); the eye of the observer, being at a height of about 4 ft. 6 in., was well above the rotating column. Thirty disturbances were observed in about twenty minutes, and in no case was the rotation other than anti-clockwise (that is, cyclonic).

It occurred to me then that perhaps a discrepancy was being introduced in observers' reports, because the level of the eye in relation to the part of the column where rotation was observed is important. A clockwise rotation looked at from below is anti-clockwise looked at from above, and an observer may be likely to look up in many cases when the 'devil' is not well defined at the ground.

An analysis of reports in which the sense of rotation is given with the observer looking down on the whirl, shows that 27 out of a total of 29 are reported as anti-clockwise (or cyclonic). Most of these observations came from one station, and observations are required from other stations before the apparently anomalous behaviour of 'dust devils' can be explained.

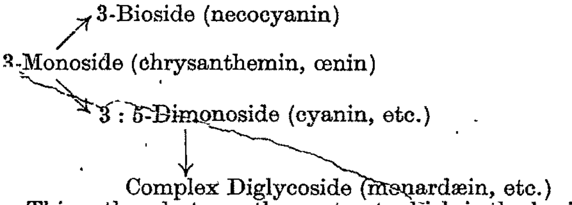
Constitution of Anthocyanins.

As the result of synthetical work in Great Britain, combined with analytical observations by Karrer and his collaborators in Zurich, the position of the sugar groups in the main anthocyanins of the pelargonidin, cyanidin, and malvidin series can be fixed with a tolerably close approach to certainty.

We suggest that pelargonin, peonin, cyanin, and malvin are not biosides at all, but are di-monosides with separate glucose residues attached to positions 3 and 5 in the anthocyanidin nucleus. Mecocyanin, prunicyanin, keracyanin, and others of similar type, are, however, biosides; the biose group being in position 3. The arguments are a little too involved to put forward here in detail, but we wish to point out that the new idea of the constitution has an important consequence.

The anthocyanins are now considered to be related as follows:



3-Bioside (necocyanin)
3-Monoside (chrysanthemin, œnin)
3 : 5-Dimonoside (cyanin, etc.)
Complex Diglycoside (monardæin, etc.)

This rather destroys the contrast which is the basis of Miss Scott Moncrieff's interesting letter in NATURE of June 27, because the two types of anthocyanin are to be regarded as brethren rather than as cousins. Nevertheless, Miss Scott Moncrieff's rule holds in the majority of cases.

We have recently examined a large number of related varieties of garden flowers, and find that the two sugar types occasionally occur in varieties of a single species; thus both types of pelargonidin diglycoside *and* both types of cyanidin diglycoside are found in different sweet-peas.

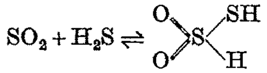
Reaction between Hydrogen Sulphide and Sulphur Dioxide.

IT is known that there is no reaction between hydrogen sulphide and sulphur dioxide in the dry state, and that mercury, benzene, or carbon tetrachloride have no effect on a mixture of the dry gases.

In the course of an investigation on the reaction between hydrogen sulphide and sulphur dioxide in non-aqueous solutions, we have found that the two gases when dissolved in benzene or carbon tetrachloride do react in the presence of mercury even when suitable precautions are taken to exclude moisture and oxygen from the reaction vessel. But a solution of hydrogen sulphide or of sulphur dioxide in either of the organic solvents has no action on the metal.

We have reason to believe that thiosulphonic acid is the primary product of the reaction between the gases:



$$SO_2 + H_2S \rightleftharpoons O_2S(SH)H$$

and that at the interface between the organic solvent and mercury the thiosulphonic acid is decomposed, producing sulphoxylic acid and the metallic sulphide. Displacement of the equilibrium in the above equation is caused by the formation of the sulphide, which lowers the interfacial tension between mercury and the organic liquid.

Further work is in progress.

A Method of Studying Surface Films.

IF a substance, for example, ergosterol, is spread in a mono-molecular layer on the surface of water contained in the tray of a Langmuir-Adam apparatus for the measurement of surface films, it is possible to make the following observations.

Where a continuous mono-molecular film is formed, one is able to see that waves, produced at the surface by a tuning-fork, show a very strong diminution of their amplitude. The experiment is very easily performed: waves are produced by an electrically-driven tuning-fork, which is in contact with the surface of the water in the tray by a dipple: the wave-length of these waves can be about 0·4 centimetre. A beam of parallel rays is thrown vertically on the surface, where it is reflected. The reflected light is concentrated by a lens (5 dioptr.) in a single point on a scale. As soon as waves disturb the surface, the point is distorted into a straight line. Now, the influence of the spreading substances is to diminish the amplitude of the waves, and this is determined by a shortening of the line of reflected light.

We have studied different substances, and have observed that not every spreading substance shows the phenomenon in the same very striking way. Nevertheless, we believe that this method of studying surface films has some advantages. It is possible to make measurements at zero pressure, and the method gives results that are very well reproducible.

Proteins also show the phenomenon.

We hope that exact quantitative measurements of the effect will enable new capillarity constants to be determined.

Insectivorous Snakes.

IN the letter of Messrs. Miller and Pagden in NATURE of May 9 it is stated that "records of insects having been devoured by snakes do not appear to be abundant". During some work on the parasites of snakes at Thandaung fifteen *Simotes violaceus* were dissected. In all cases the stomach and intestine were full of insect remains, sometimes very tightly packed and completely filling the lumen, chiefly those of a small brown grasshopper. In only one case were any vertebrate structures found: a small newt and a viper's tooth. Remains of insects were also found in *Natrix piscator*, *N. chrysargus*, and *Trimeresurus gramineus*.

Research Items.

Social Organisation in Manoa.—Miss Margaret Mead, while engaged during 1925–26 in a study of the adolescent girl in Samoa, was brought into exceptionally intimate touch with every household group in three villages on the north-west coast of the island of Tau, Luma, Siufaga, and Faleasao. Her observation of Samoan theory and practice in social organisation, which differ considerably *inter se*, are published as *Bull.* 76 of the Bernice P. Bishop Museum. The Samoan social organisation is an amalgamation and recombination of several distinct principles: hereditary rank, the functions and privileges of relationship groups, and the recognition of the organised village community with rights and privileges of its own. The dominant note in Samoan society is that all a Samoan's interest, all his emotion, is centred in his relationship with his fellows within an elaborate social pattern. Individual work and play, religious activity, art and personal relationship have never been admitted and receive scant attention from the society. All attempts at a development of personality along other than social lines are neglected and wither away. The taboo against a woman touching the bonito canoe is a survival, for such a taboo on women against the canoe as is found in the Marquesas and New Zealand has no place in Samoan culture, because neither men nor women in Samoa have any importance in themselves until translated into a social scheme. Thus the entry into a kava ceremony by a woman who had no right to be there might completely invalidate a whole communal undertaking, but not on account of her essential female potency, which here is negligible. With this emphasis on things done within the social pattern goes the complementary feeling that things done alone are suspect, if not downright wrong. The expectant mother, the young chief, and the bride-to-be must never be alone. This militated against the development of individual communion with the supernatural and against the formation of secretly cherished magical formulæ.

Indian Terra-cottas.—In the *Indian Antiquary* for August, Mr. K. de B. Codrington discusses the difficulties of dating Indian terra-cottas. Very few have been placed stratigraphically. There are four main groups of material for dating. (1) Two figurines, a rabbit, or cow, and a bridled horse, were found on the level of the brick floor two feet above the plinth of the southern of the two Râmpurvâ pillars. (2) *a*, Group of four figurines from Nîlgiri graves, mostly from pot-covers, in the British and Madras Museums: these are roughly modelled figures of men, women, and animals, hand-moulded with sticked-in details; *b*, a group excavated at the Bhir mound, among them a toy horse ascribed to the 'pre-Mauryan' period; *c*, fragmentary terra-cottas found in the monastery mound at Shâh-jî-kî-Dherî, a Græco-Buddhist site with Gupta surface finds. (3) Numerous terra-cotta figures excavated at Basârh, attributed to Kushan, Sunga, and Mauryan age, on slender evidence. A second group from this site is of importance. The figurines are of coarse workmanship, the eyes being represented by circles. They are from the same level as a seal ascribed palæographically to the fourth century. (4) Gupta fifth and sixth century terra-cottas. Dr. Coomaraswamy has recently compared figurines with the terra-cottas of the 'Indo-Sumerian' culture of Harappa and Mohenjo-Daro of 4000–3000 B.C.; but nothing from the two sites affords exact parallels. They are primitive only in the sense that they are very crude. Five of these figures have recently been acquired by the Indian Museum, South Kensington. Though technically they partake of the tradition of both Basârh and Shâh-jî-kî-Dherî, they belong rather to the finer Basârh. The technique and the details of the hairdressing and jewellery all point to the late second-first century B.C. as the date of origin.

Mammals of an Island Group (Pityusa).—The island group of Pityusa, of which the chief island is Ibiza (or in the "Times Atlas", "Iviza", grouped with the Balearic Islands), lies between the Balearics and the mainland of Spain. The mammal fauna, described by Dr. Otto Koller (*Sitzunsber. Akad. Wien*, Abt. 1, Bd. 140, p. 57; 1931), includes only ten species, but like most island faunas, presents features of great interest. There are endemic forms such as *Genetta* and *Erinaceus* and, perhaps, also *Crocidura*, all derived from the original fauna of the southern Spanish mainland; and it is evident that the basic fauna is common to the Balearic Islands and Pityusa. The separation from the mainland must have taken place in Pliocene times, but only later were the two island groups themselves separated. Thereafter, two new linkages appear to have taken place: a land-bridge between Pityusa and southern Spain permitted the immigration of *Martes foina mediterranea* and *Crocidura russula pulchra*, which are absent from the Balearics; while a union between the latter and the Corsica-Sardinia region gave them, instead, *Martes martes latinorum* and *Mustela nivalis boccamela*.

Disease-Resisting Turnips.—Trials with turnips at Craibstone, Scotland, described by W. M. Findlay (*Scottish Journal of Agriculture* (vol. 14), on land which is badly infected with finger-and-toe disease, have brought to light a disease-resisting variety. Although the history of this turnip, recorded under a variety of names, can be traced back for nearly one hundred years, its valuable properties do not seem to have been fully recognised. The Bruce, as it is proposed to call it, is a purple-top yellow turnip, of the dark-coloured bottom and flesh type, with certain additional characteristics such as purple colour in the ribs and veins of the leaf. The percentage of the dry matter in the Bruce, a property usually taken as an indication of quality, was found to be higher than that in a number of other types of turnip, and it also proved of equal feeding value to Green-Top Yellow (Challenger) in a milk production trial. As regards cropping on healthy soil, the Bruce headed the list of five varieties if the yield was reckoned on a dry matter basis; and when grown on land infected with finger-and-toe disease, it was the only strain that produced a good crop. Complete immunity is not claimed for the Bruce. Infection, however, appears to be confined to the roots, the bulbs themselves being rarely injured. The seed is small but germinates well, and is recommended in preference to larger seed of an inferior strain. Sowing on infected ground is advised if the crop is to be grown for seed, in order to maintain, and increase if possible, its disease-resisting properties.

Kansas Permian Insects.—A series of papers on Kansas Permian insects by Dr. R. J. Tillyard has been published during the last few years in the *American Journal of Science*. The present contribution (Part 13) deals with the new order Protelytroptera and appears in vol. 21 (March 1931) of the periodical mentioned. The fossils in question include seventeen specimens, of which four are more or less complete, and from a study of their characters Dr. Tillyard concludes that they are neither true Coleoptera nor ancestral to that order. After taking various possibilities into account, he comes to the decision that these fossils represent the ancestral group from which the existing order Dermaptera, or earwigs, has been derived. At the same time he suggests that the fossil remains that form the order Protocoleoptera may have been a remnant, which found refuge in Australia, of this new order. The solution of the affinities of the Protelytroptera is bound up with the venation and the method of folding of the hind wings, which appear to approach the earwig type more closely than any other. The elytra, or fore wings, on the other hand, are very much less shortened and of the nature of normal convex, hard wing covers. Not very much evidence is to be obtained from other parts of the body, but there appears to be no features directly contrary to the hypothesis that the order is ancestral to the Dermaptera. The new order is divided by Dr. Tillyard into no less than five families, including seven genera and eleven species.

Phenomena of the Upper Atmosphere.—Prof. S. Chapman's Bakerian Lecture, which is published in the August issue of the *Proceedings of the Royal Society*, summarises a number of efforts which have been made to attack mathematically the problems connected with dissociation and allied phenomena in the upper air. Although many of the numerical values of atomic constants which it is necessary to introduce are known only approximately, very considerable progress has been made, largely by Prof. Chapman himself, in the interpretation of existing observational data. Prof. Chapman has shown, for example, that the quite large amount of energy which is emitted in the form of general green auroral radiation during the course of a night is probably stored up as energy of dissociation—perhaps including ionisation—during the daytime; recombination is a process the rate of which is largely controlled by density, whilst the emission of light from the metastable atoms of oxygen which give the green line takes place, so far as is known, within a second or less of the formation of the atom, independently of the presence of other atoms or molecules, and hence these metastable atoms must have relatively long-lived ‘ parents ’. It follows from similar considerations that the emission of the green line probably occurs between heights of 100 km. and 200 km. Prof. Chapman discusses the origin of the ionisation in the main 100 km. layer which is responsible for the majority of ordinary atmospheric wireless phenomena, and shows that there is much support for the view that it is caused by a stream of neutral particles from the sun; he also suggests that the positive ions present in this layer are mainly molecular nitrogen, whilst those in Appleton's upper ionised layer are atomic oxygen. The position of the upper layer and the maximum density of electrons in it can be predicted very satisfactorily from the hypothesis that its ionisation is due to ultra-violet radiation.

Origin of γ-Rays.—In a paper in the August number of the *Proceedings of the Royal Society*, Lord Rutherford and Dr. C. D. Ellis discuss the nature of the nuclear changes which lead to the emission of γ-rays. Their starting point is the now well-established fact that many α-particle emitters give not a single α-particle but a group. The implication is that the α-particles in the nucleus can exist in states of different energy, and it is a reasonable hypothesis that transitions of the α-particles between these states occur in which γ-rays are emitted or the available energy is transferred directly to an extranuclear electron in the atom. There is strong evidence that energy differences in the α-particle groups for a given element are connected numerically with the energy of its γ-rays, but since the energy of α-particles can be found only rather less accurately than the energies of γ-rays, the numerical data used in this paper are drawn from measurements made upon the latter. The particular model of the nucleus of which use is made is one in which different numbers of α-particles are excited to the same quantum state, apparently the exact opposite of what occurs with the extranuclear electronic systems, where such an arrangement is eliminated by the Pauli exclusion principle. From this it is shown that it would be expected that the energies set free in transitions should be given to a first approximation by an expression of the form $E=pE_1-qE_2$, p and q being integers, E_1 a difference in energy of two states (in the ordinary sense), and E_2 a smaller energy of interaction. This prediction is finally tested by making a diagram with the energies of the γ-rays shown as ordinates against integers as abscissæ, the points being placed so as to lie on diagonal lines. In the diagram given for radium C′, six diagonals are required for some forty γ-rays, and the fit is, on the whole, excellent. The same is true for a smaller number of rays from radium B. In addition to this detailed numerical work, the paper contains a discussion of a number of other points—in particular, the probability for various types of transitions of the α-particles.

The Photoelectric Effect.—The first July number of the *Physical Review* contains a paper by R. H. Fowler, analysing some recent careful experimental work on the effect of temperature on the photoelectric current from clean metals in monochromatic light. The experiments show that there is no sharply defined maximum wave-length for emission of photoelectrons, but that the photoelectric sensitivity falls off gradually at low frequencies, especially at the higher temperatures, so that the sensitivity curve can be followed to a frequency determined primarily by the delicacy of the current measuring device used. Mr. Fowler shows that these results are to be expected from Sommerfeld's theory of metals, and can be completely accounted for by the change in the velocity distribution of the electrons inside the metal with temperature. From the theory a graphical method has been developed for finding the work required to extract an electron from the surface, which makes use of the general form of a whole family of sensitivity curves, and is more certain than previous methods for finding the work function from similar data. At the same time, Mr. Fowler shows there is a necessary uncertainty of about one per cent in the results, so long as an ambiguity in the theory of photoelectric emission remains unresolved. The work-functions for silver, gold, and tantalum are 4·74 volts, 4·90 volts, and 4·12 volts respectively.

Organic Acids in Plants.—Nelson and Mottern, in the August number of the *Journal of the American Chemical Society*, describe investigations of the organic acids in barley, maize, oat, and rye plants. These all contain aconitic acid, which is also present in wheat, sugar cane, and sorghum. Oxalic, malic, and citric acids are also present. Barley contains malonic and tricarballylic acids, whilst maize contains no malonic acid but tricarbalyllic acid. The percentages of oxalic acid in the fresh plants varied from 0·019 (barley) to 0·048 (rye).

Organic Gold Compounds.—The use of the Grignard reagent in the preparation of organic gold compounds has been shown to be limited to the ethyl radical and less electronegative radicals. In the August number of the *Journal of the American Chemical Society*, Kharasch and Isbell describe the action of anhydrous gold chloride on aromatic compounds, which is found to lead to the introduction of gold into the aromatic nucleus and the formation of a compound, $RAuX_2$. Direct 'auration' is thought to be as general a reaction as nitration, halogenation, or mercuration, except that it is much more rapid and the products are much less stable. Nitrobenzene, however, dissolves gold chloride without undergoing reaction. Phenyl, tolyl, and diphenyl auric dichlorides, methyl salicylate auric dichloride, and *o*-nitroanisole auric dichloride are described. The second paper deals with the gold imide compounds. The gold imide complexes are very stable, and do not give tests for gold with stannous chloride or oxalic acid. They are represented by the general formula $H^+[Au(imide)_4]^-$, and are called imido-auric acids on account of the similarity of their structure to that of chlorauric acid. They are obtained by direct combination of auric hydroxide and the imide. Succinimido-auric acid is a stronger acid than carbonic acid.

Insulation of Overhead Transmission Cables.—At the international conference of high-voltage electrical engineers which met in Paris recently, H. O. Austin read a useful paper on the insulation of overhead lines for high pressures, an account of which is given in the *Electrician* for Aug. 7. He stated that increasing the number of insulators does not necessarily diminish the number of breakdowns on a transmission line. It may, in fact, increase the number of transient currents due to switching operations or to lightning. Many operating records show that troubles arising from sudden 'flashovers' of the current over strings of insulators, due to the line either being directly struck or having high voltages induced in it by lightning flashes, are greatly increased by great height. He mentioned that the 220-kilovolt line of the Hydro-Electric Commission of Ontario, which uses short spans and has the earth and conductor wires at relatively low heights above the ground, has been working very satisfactorily. Owing to the appearance of corona discharges when the three-phase lines are close together, it is usual to put them several feet apart. This increases the reactance of the line and the cost of its erection. He suggests that the conductors should be coated with a suitable insulating paint or covering so as to prevent the formation of the corona and permit close spacing. This seems to us an excellent suggestion. If the thermal conductivity of the paint were high, its use would appreciably increase the carrying capacity of the line. In addition, it would go a long way towards preventing interference with radio communication, which is serious when brush discharges take place. The presence of dew in the early mornings on lightly loaded lines favours these discharges and sometimes causes the line to flashover. A slight temperature increase of the lines, obtained, for example, by allowing a large current to flow for brief periods, would prevent the formation of dew.

Astronomical Topics.

The Mass of Neptune's Satellite, Triton.—We learn from a *Daily Science News Bulletin* dated July 30, issued by Science Service, Washington D.C., that an attempt has been made to obtain this mass with the 60-inch reflector at Mount Wilson by Dr. S. B. Nicholson, Dr. A. van Maanen, and Mr. H. C. Willis. A series of photographs of Neptune were taken when near its stationary point, so that the same comparison stars could be employed for several nights. The method, of course, involves the determination of the small shift of Neptune due to its motion round the common centre of gravity of itself and Triton. The problem is evidently rather too difficult for solution at present, as the values obtained for the mass range from 0·01 to 0·04 of that of the earth. The first value is a little less than that of our moon, the second is about equal to that of Mercury and to the largest satellites of Jupiter and Saturn. It might have been anticipated *a priori* that the mass of Triton probably lies between these limits. It is conjectured in the above *Bulletin* that the mass of Pluto may be about the same as that of Triton; but there seems to be good reason for thinking that Pluto's mass is considerably greater than the above values.

Lunar Circles.—In a note appearing in the issue of *Scientiarum Nuncius Radiophonicus* for June 25, under the heading "Johannes Boccardi—De efformatione circorum lunarium", the ballistic theory of the origin of lunar circles is discussed. This theory regards the circles as the results of deformations of the moon's surface caused by shocks produced by enormous celestial projectiles. It does not seem possible that such projectiles could have been small satellites of the earth captured by the moon, so that they could only have been gigantic meteorites. This view the author decides to be improbable for various reasons. First, although the earth has a surface area thirteen times as great as that of the moon, there is no evidence that it has ever been struck by projectiles of the dimensions necessary to form the lunar circles. The only terrestrial formations analogous in any way to these circles occur in Arizona and are on a vastly smaller scale. Moreover, the fact that the lunar circles lie in chains indicates a common and approximately simultaneous origin. The most powerful telescopes fail to reveal any such circles on the planet Mars. In the light of these considerations, the author deems the ballistic theory of this phenomenon to be untenable.

Comet Notes.—Prof. G. van Biesbroeck contributes to *Astr. Jour.* No. 958 a discussion of the definitive orbit of the comet 1925 *j* = 1925 VII, which he himself discovered on Nov. 1, 1925, in the same telescopic field as 1925 *c* (Orkisz), which he was observing. 280 observations are used, extending over seven months. The following hyperbolic orbit was obtained:

$$\begin{array}{rl} T & 1925 \text{ Oct. } 2{\cdot}97348 \text{ U.T.} \\ \omega & \left.\begin{array}{rrr} 106^\circ & 24' & 12{\cdot}0'' \\ 334 & 33 & 43{\cdot}4 \\ 49 & 19 & 15{\cdot}9 \end{array}\right\} 1925{\cdot}0 \\ \Omega & \\ i & \\ \log q & 0{\cdot}1948557 \\ e & 1{\cdot}0004276 \end{array}$$

The excess of *e* over unity is eighteen times its mean error, so it is well established. He then applied perturbations by Jupiter and Saturn for the seven preceding years (on the lines adopted by Prof. E. Stromgren), and found that on Feb. 19, 1918, the orbit was elliptical with *e* 0·999820 and period 811,000 years. This is referred to the centre of gravity of sun, Jupiter, Saturn. It is shown that the orbit previously to 1918 was permanently elliptical. This result agrees with that for all other comets that have been similarly tested.

It would be interesting in these cases to trace the comet's course in the future, as well as in the past. The departure of a comet from the solar system would be nearly as interesting as the introduction of a comet from outside the system.

Echinoderm Larvæ.

PROF. MORTENSEN'S "Studies of the Larval Forms of Echinoderms", reviewed in NATURE for Dec. 8, 1921, is well known. He has now issued two sets of additional notes,* one resulting from a visit to Amboina and the Kei Islands in 1922 and a journey to Java, Mauritius, Cape Town, and St. Helena in 1929–30, the other describing observations made at the Swedish Zoological Station of Kristineberg in 1918. These notes are directed to making known the form of the various larvæ, with the view, first of correlating the larvæ with the adults of their species, and secondly of seeing what light their comparison may throw on the relationships of species, genera, and families. The memoir includes a summary of similar observations published since 1921 and is noteworthy for the beautiful illustrations, many in natural colours, by the author himself.

Difficulties inseparable from travel and especially an unfortunate accident with fouled water make the notes less complete than was hoped, but many points of interest are recorded. For example, the form previously described as *Echinopluteus transversus* is now unexpectedly found to belong to *Diadema* and possibly allied genera. The inference from its muscular system that this larva must swim by moving its long post-oral arms is now confirmed by observation; the movements are quick, rhythmical, and interrupted, recalling the jerky motion of puppets. Certain observations on cultures of these larvæ showed how dependent the rate of development is on physical conditions. Retardation increases the possibility of transport by currents, and is a factor in the geographical distribution of adults.

Turning to brittle-stars, one notes that two species of *Ophiactis* prove to have the same type of larva, so that in this class also the larval form may have a bearing on classification. On the other hand, a star-fish, *Archaster typicus*, differs from the somewhat similar *Astropecten* in the possession by its larval form of a Brachiolaria stage. The question arises whether the Brachiolaria or Bipinnaria stage is the more primitive, and Prof. Mortensen again gives reasons for regarding the simpler Bipinnaria as the forerunner of the Brachiolaria. This may be, and yet the conclusion that the brachiolarian sucker is not homologous with the pelmatozoan stalk may not follow, for, as Prof. MacBride insists, the fixed stage may have been dropped by *Astropecten* and similar forms as unsuited to their muddy or sandy habitat. It is to be noted that the two or possible three species in which Prof. Mortensen detects a brachiolarian stage live on or near hard coral-reef.

The larvæ of allied forms often manifest other differences, which, while seeming to be fortuitous variations, may depend on some physical factor. Thus in many ophiurid larvæ the front 'arm' on the right is longer than that on the left, and in one species it also loses its band of cilia. More curious is a difference in the development of the hydrocoel ring (the rudiment of the water-vascular system): in *Amphiura filiformis* the hydrocoel in forming this ring grows upwards and bends round above the œsophagus; in *Ophiura albida* it bends below the œsophagus to achieve the same ultimate result.

This selection may conclude with a couple of notes on adult sea-stars. In two species of *Archaster* "a kind of copulation takes place, the male lying on the back of the female"; his rays alternating with hers. A small fish, *Fierasfer*, has long been known to take shelter within various Cœlentera and Echinoderma, but Prof. Mortensen has found it within the actual body-cavity of two species of the cushion-shaped sea-star *Culcita*. Since the body-cavity of an echinoderm has no direct opening to the exterior, the occurrence offers as great a puzzle as how the apples got into the dumplings. Prof. Mortensen suggests that the fish enters the sea-star's mouth and bites a hole in the stomach wall through which it enters the body-cavity; it probably feeds on the genital organs, and, when it wants to breed, bites its passage out again.

Prof. Mortensen has brought back much from his travels and has shown how much more there is to be learned in these tropical regions if only better aquarium facilities could be provided.

F. A. BATHER.

The Artificial Coniferous Plantation and its Place in Forestry.

THE afforestation programmes being undertaken in New Zealand by private companies and the State Forest Department have been the subject of comment in NATURE (Feb. 14 and April 18, 1931). That further consideration of these programmes would appear to be not without its importance is brought about by the opinions expressed by the Director of the State Department on the subject of artificial coniferous plantations versus indigenous forest, a question which at the present day has almost a world-wide importance. Mr. E. Phillips Turner, Director of Forestry in New Zealand, in answer to frequent demands on the subject, has prepared a brochure (*Circ.* No. 31, N.Z. State F.S., 1931) entitled "Trees used in State Afforestation in New Zealand". The Circular should be consulted for the valuable information given under each of the chief species (mainly conifers) made use of. These may be noted as *Pinus ponderosa*, *P. laricio*, *P. radiata*, Douglas fir, larch (*Larix europœa* and *leptolepis*), *Sequoia sempervirens*, *Cupressus Lawsoniana*, *Thuya plicata*, *Pinus strobus*, *P. muricata*; and a few others of lesser importance. Eucalypts were originally grown on a considerable scale in the early years of the work of the State Forest Department; they are, however, so subject to attacks of various insects that they are not now being planted. Poplars are being experimented with and are thought to have a considerable future.

The great temptation to concentrate on the artificial conifer plantation is due to the extraordinary rapidity of the growth of some of the exotics in New Zealand. That every country is adopting a correct policy in endeavouring to provide, in so far as possible, for its own requirements in coniferous softwoods is conceded. But the time would appear to have arrived when a halt should be called in a policy which seeks to substitute the artificial coniferous plantation (planted, it may be admitted, on areas of poorer soil) for the valuable indigenous hardwood forests of the country, the ultimate disappearance of which under the axe of the exploiter or by fire is being accepted as inevitable.

The Director of Forestry states that experiments are being made to test the practicability of re-establishing the native softwoods in cut-over State forests, when the land is not suitable for farming. Experiments are being made with Kauri, the New Zealand valuable timber tree, "to test the practicability of working a Kauri forest on a sustained yield plan" and the possibility of re-establishing Kauri on tea-tree scrub lands which formerly carried Kauri forest. As regards indigenous hardwoods, the various species of southern beech (*Nothofagus*) are said to be quick growing. Beech forests are therefore to be managed for the production of future hardwood requirements.

The concluding paragraphs of the brochure sum up the opinions held by the State Forest Department. It is pointed out that, after the naturally-grown forests of native trees have been cut over, there will be an end of the splendid wide and clean boards now being obtained, and that thence boards of natural timber will be mostly narrow and more or less knotty, such as the red and white Baltic deals exported to Great Britain (the writer must be confusing the British-grown material with that of the Baltic, which usually is free from knots). Secondly, it is anticipated that fabricated boards, etc., made from disintegrated wood will largely replace natural timber, and knotty timber can be used for the former without any serious difficulty. Thirdly, and in spite of the recognition by the Forest Department that they must eventually disappear, it is said that it will be apparent to all "that the remaining splendid stands of indigenous timber, which Nature has provided us, should be used with the greatest care and economy".

Attention has been directed (NATURE, Feb. 14) to the private companies which have been formed in New Zealand to promote afforestation work. Many of these companies have been federated into an Association which represents a combined capital of £5,000,000. The objective of these companies is the ultimate afforestation of a million acres of exotics. It is recognised that this work to be done expeditiously is a purely business proposition, quite outside the capacity of a State Department, which could not be granted the funds from the public purse to carry it on with such rapidity.

As a result of the War, several of the European countries are making arrangements to increase their areas of coniferous softwoods. In France, for example, there are extensive stretches of very poor heather, etc., clad lands in the Plateau Central, for the afforestation of which an extensive propaganda is being carried on. Whilst the Government Forest Department is undertaking a certain amount of work, the aim is that the greater part of the afforestation work shall ultimately be done (with grants when necessary from the State) by the private proprietor and the village communities owning the land. But this recognition does not involve the sacrifice of her magnificent hardwood forests, chiefly of oak and beech, which have been under an increasingly fine management since the days when Colbert (1660) first ordered an investigation into the methods in force in the State forests.

With such examples before her, it would appear to be an irremediable disaster for New Zealand to sacrifice those of her fine indigenous forests still left, without an effort to save them, and the markets dependent upon them, for future generations.

The Mellon Institute.

ON the occasion of the award of its medal to Messrs. A. W. Mellon and R. B. Mellon, the founders of the Mellon Institute of Industrial Research, Pittsburgh, U.S.A., the American Institute of Chemists has devoted an issue of its bulletin to an account of the inception and progress of the Institute. According to the *Chemist* for April, its foundation in 1913 was a direct result of the success of the inauguration of the industrial fellowship system in the University of Pittsburgh. Twenty years after the adoption by Dr. R. K. Duncan of this method of combining education with industrial profit there are in operation sixty-four such fellowships, the work being conducted by 109 fellows and 31 assistants. The extent to which the value of the Institute as a servant to industry has been realised may be gauged by the fact that for ten years after its establishment, in accommodation believed to provide for future growth, the waiting list was almost as long as the list of companies whose problems were already being investigated.

A new home, some three hundred feet square and eight stories high, and designed in the Ionic style, will be a notable monument to the economic success of industrial research and the esteem in which the organisation is held in a progressive industrial country.

The industrial research carried out by the Institute is organised on a contract basis. The problem is set by, and the results become the property of, the donor of the fellowship; the worker is found and engaged by the Institute and provided with the broadest facilities for a minimum period of one year. Only one investigation is carried out on a particular subject at any one time. The prosecution of fundamental scientific investigations is not neglected, funds being available for application to this essential precursor of industrial development. All questions of publication, patent protection, or advertisement are determined by consultation with the donor, whilst all forms of co-operation which do not violate the necessary limits of confidential operation are encouraged.

The Institute stimulates the holders of fellowships to put forth their best efforts by affording both freedom and sustained support. Besides creating new industries and strengthening old ones it has thus produced a body of trained and practised investigators, who have played no small part in advancing the industrial position of the United States of America.

On its educational side, the Mellon Institute is worthy of special attention. The education which is afforded is not merely scientific, but also social; it is concerned with the personal and official duties of research staffs, with commercial procedure, with professional ethics, and with industrial psychology. The worker is trained to convey and interpret the results of his scientific work to the non-scientific business man in such a way that the latter can estimate its commercial value and appreciate its possibilities. The effort is being made to raise the professional status of the research worker by encouraging the proper type of man to engage in scientific professional work, and by improving his economic position. Equally important is the effect on the outlook of those entrusted with the direction of affairs, both in individual industries and in national and international trade.

The increasingly dominant position of science cannot be overlooked, and it becomes essential in the modern world that those who are given responsibility should also be equipped with knowledge. America is justly proud of the Mellon Institute; it is an institution which deserves the careful study of progressive nations.

Rock-Paintings in North-West Australia.

THE paintings in rock-shelters and caves of north-west Australia, which differ in type from those of other parts of the continent, were first seen and described by Sir George Grey in 1839. These paintings and others from adjacent sites have now been examined by Mr. A. P. Elkin, who has discussed their meaning with the Ungarinyin tribe of Walcot Inlet. The results are published in *Oceania*, vol. 1, No. 3.

In one of the caves, it has been customary to deposit the bones of the dead after they have been exposed in platform-burial and 'cried over'. This is a great honour, only conferred on fully initiated men who die before they are old enough to be considered 'close up' dead. The bones are painted with red ochre "to keep them clean". Each horde has its own picture gallery. The paintings are in black, white, red, and yellow. One case of the use of blue is recorded. The most remarkable painting is that of a man placed horizontally and thirteen feet from crown of the head to sole of the foot. Smaller figures near-by, two of them female, are his 'children'. He has eyes and nose but no mouth, a peculiarity of all the human figures, the natives saying that "it cannot be done". The face is partly surrounded by a horseshoe-shaped head-dress representing the band of red ochre which the natives paint on the forehead and the face. Projecting from this are red lines with black tips representing the hair. Small round rings near the feet are a ground fruit, *nalgo*.

The paintings as a whole may be divided into representations of the human figure, especially the head; various objects, such as the sun, water-lilies, *nalgo* fruits, snakes, crocodiles, kangaroos, and the like; and, lastly, stencilled hands. Some of the paintings are obviously of a considerable age and are partly obliterated. The natives say they do not make these pictures; but they retouch them. The heads without mouths are retouched as a rain charm, usually just before the wet season, but the charm is effective even in the dry season. Rain is the totem of the horde. If the headman dreams that he has retouched the figures, it is equally efficacious. Connected with their significance as the power that brings rain is the association with the 'rainbow-serpent', which is sometimes regarded as the totem of the head figures, a snake being shown with them. The retouching of the female figures causes an increase in babies, which the rainbow spirit makes and brings to the water-holes in the rain. Retouching the animal and vegetable figures leads to an increase of the species depicted.

Radioactivity and Earth Movements.

THE Geological Society of Glasgow has published (*Trans.*, vol. 18, pp. 559-606) a lecture by Prof. A. Holmes, given in 1928, which he has expanded into a valuable memoir on the cause and distribution of the major movements in the earth's crust.

The fundamental fact in geological history is the alternation of periods of powerful earth movements and active vulcanism with long intervals of repose. Prof. Joly explained this alternation as due to the accumulation of radioactive heat and its escape at periods of diastrophism. That theory has been generally rejected owing to its lack of agreement with the main facts of geological history. Prof. Holmes upheld it in a modified form; but he has now abandoned it. He retains the action of radioactive heating, and rejects J. W. Evans's suggestion that the heat thus generated has been used in physical changes in the minerals around the disintegrating radioactive material.

Prof. Holmes attributes the main earth movements and crustal disturbances to convection currents in the fluid substratum. He establishes the existence of this fluid layer in his preliminary discussion, which includes a critical summary of recent literature on the major structure of the earth's crust, and of the evidence given by near earthquakes. Amongst other instructive conclusions are that "we may regard the Pacific crust as being like that of the continents" (p. 570). Prof. Holmes regards the primary convection currents in the fluid substratum as analogous in direction to those in the atmosphere, and corresponding in directions to those of the trade winds and monsoons. The persistent trend in one direction would therefore occasion continental drift, at a rate which Prof. Holmes estimates at three miles in 100,000 years. The formation of the Atlantic basin by such drift would take 100 million years.

The paper shows many striking agreements between the main mountain lines, the ocean basins, the distribution and origin of rift valleys, and oceanic transgressions and those that would result from such deep-seated currents. Isostasy is accepted for minor modifications of the main structures.

Acceleration of Fermentation by Algæ and Sea-water.

THE results of investigations carried out during the past few years show that alcoholic fermentation is accelerated (1) by the various vitamins to different extents, and (2) by cholesterol and ergosterol, which are supposed to contain, in greater or less proportion, the provitamin of growth. In view of the fact that, apart from the organic materials dissolved or suspended in sea-water, marine algæ constitute, either directly or indirectly, the sole food of marine animals, it seemed of interest to ascertain what effects these algæ would exert on the course of fermentation.

In the *Atti della Reale Accademia Nazionale dei Lincei* for Jan. 18, Dr. Pirrone, of Messina, describes experiments which demonstrate that *Ulva lactuca* (*L.*) *Lejol*, either in the fresh state or when dried, accelerates the fermentation of glucose very considerably. This effect is due to the presence in the alga of one or more organic substances, probably existing as sols, which are soluble in water, alcohol, or ether at the ordinary temperature.

Experiments made by De Fazi in 1927 yielded results which indicated that the velocity of the alcoholic fermentation of glucose solutions prepared with distilled water, previously sterilised and subjected to the radiations from a quartz mercury vapour lamp, was appreciably greater than that of a similar solution made with sterilised water which had not been exposed to such radiations.

Further experimental data communicated by Sanzo and Pirrone to the Accademia dei Lincei on Jan. 18 now show that freshly collected sea-water, if added to glucose solutions in proportions not exceeding 20 per cent, causes a marked increase in the velocity with which such solutions are fermented by yeast. If the sea-water is kept for about twenty-four hours after collection before being added to the glucose solution, this accelerating influence diminishes slightly in degree to a value which does not change with further storage of the water. The maximum effect is observed when the glucose solution contains about 13 per cent of sea-water, and increase of the percentage above 20 is accompanied by progressive diminution in the velocity of fermentation.

University and Educational Intelligence.

CAMBRIDGE.—Dr. A. Harker, St. John's College, has resigned his readership in petrology as on Sept. 30, and, in view of the recent replacement of the professorship of mineralogy by a professorship of mineralogy and petrology, the General Board does not intend to recommend to the University the continuation of the readership.

Dr. F. R. Winton, Clare College, has been appointed University lecturer in physiology for three years, and Dr. E. G. Holmes, Christ's College, has been appointed University lecturer in pharmacology for three years. Dr. T. W. Wormell, St. John's College, has been reappointed observer in meteorological physics for five years.

THE Council of the Institution of Naval Architects has awarded the Elgar Scholarship in Naval Architecture (1931)—£130 per annum for three years at Armstrong College, Newcastle-on-Tyne—to Mr. H. Lackenby, of Messrs. R. and W. Hawthorn Leslie and Co., Hebburn-on-Tyne, and the Earl of Durham Prize to Mr. J. A. Price, of H.M. Dockyard, Sheerness.

THE University of Cambridge has issued a pamphlet containing summaries, extending, on an average, to a page and a half, of 72 dissertations approved during 1929–30 for the Ph.D., M.Sc., and M.Litt. degrees. More than half of the candidates had come to Cambridge after taking their first degrees in other universities—14 in English universities, 5 in Australian, 16 in universities in other parts of the British Empire, and 4 in the United States of America. Ten were women. The dissertations are classified under departmental headings as follows: mathematics 10, physics 9, chemistry 8, botany 8, biochemistry 6, other departments of science 16, other departments 12. The corresponding figures for the preceding year are: chemistry 9, agriculture 6, geology 6, biochemistry 6, mathematics 4, botany 4, other science departments 9, other departments 12. Of the three candidates in the department of English, two were from the United States of America and one was from Aberdeen. It would be unscientific to infer that English, like the proverbial prophet, is not without honour save in her own country, but this distribution of the Cambridge candidates for higher degrees in English seems significant.

AMERICAN educational progress in 1930 is briefly reviewed in the January issue of *School Life* by a member of the staff of the Federal Office of Education. The enthusiasm for educational research displayed by Federal and State authorities and voluntary organisations is astonishing. The Federal Government has just completed a survey begun in 1927 of land-grant colleges, is half-way through a survey of secondary education to be finished in 1932, and has begun a survey, for which Congress appropriated 200,000 dollars, of the professional education of teachers. Educational problems of every kind are being subjected throughout the country to scientific examination with scant regard for traditional prejudices and with confidence in America's ability to find the right solutions. "No longer do school boards send delegates abroad to bring back ideas for our democracy. Our rapid advance in the sciences basic to education and our supremacy in mechanical lines open for us the road to world leadership." There is likewise a remarkably widespread ambition on the part of teachers to improve their qualifications. Summer schools in 1930 were attended by 421,000 teachers, or about 45 per cent of the total number.

Birthdays and Research Centres.

Sept. 6, 1870.—Prof. F. G. DONNAN, C.B.E., F.R.S., professor of general chemistry in the University of London, the Sir William Ramsay Laboratories of Inorganic and Physical Chemistry, University College.

The chief subjects under investigation at present in the laboratory which I have the honour to direct are as follows: Colloid sols and gels, electrochemistry, photochemical actions, absorption of light in the visible and ultra-violet, X-ray analysis, surface phenomena and molecular films, catalysis, heterogeneous reaction kinetics, chemical and other effects of electrical discharges in gases (active molecules and atoms), infra-red absorption and molecular structure, magnetic susceptibilities of chemical systems, dielectric phenomena and dipole moments, properties of highly dried liquids, scattering of light in liquids. The possibility of investigating such a wide variety of phenomena is due to the generosity of Imperial Chemical Industries, Ltd.

Sept. 6, 1876.—Prof. J. J. R. MACLEOD, F.R.S., regius professor of physiology in the University of Aberdeen.

It is generally recognised that carbohydrate metabolism is partly under the control of the nervous system, and so-called diabetic centres have been described in various regions of the brain. Donhoffer and I are finding that a lesion involving the anterior region of the pons but of no other region of the brain causes a marked hyperglycæmia, and that this occurs whether or not glycogen is present in the liver. The muscle glycogen is rapidly used up as a result of the lesion. It fails to produce hyperglycæmia after removal of the adrenal glands. Its effects are annulled by insulin. A method has also been evolved for the measurement of the amount of insulin in blood, and it is hoped that it will be possible by its use to supply direct evidence as to whether the internal secretion of this hormone varies under various physiological and pathological conditions in the manner described by other investigators using indirect methods.

Sept. 6, 1892.—Prof. E. V. APPLETON, F.R.S., Wheatstone professor of physics, King's College, London.

For some years now I have been specially interested in various geophysical problems, the chief of which has been the determination of the electrical structure of the upper atmosphere, using wireless waves as the exploring probe. The method of experimental attack used has been to send vertically upwards wireless waves of different frequencies and make observations on them when they return after being reflected at high levels. Thanks largely to the energy and skill of a group of investigators working for the Radio Research Board of the Department of Scientific and Industrial Research, whose efforts I have been permitted to direct, a large mass of information relating to the heights reached by waves of different length has been accumulated. Since different concentrations of ionisation are required to turn back waves of different length, it is readily seen that the data mentioned yield information relating to the variation of ionisation content with height.

Up to the present a fairly complete study has been made of the diurnal and seasonal variation of the ionisation in the lower of the two ionised regions which have been found to exist, and attention is now being directed to similar observations for the upper region, which is found to be richer in ionisation. It is hoped to continue these measurements for at least one eleven-year sunspot cycle.

The results of such observations in England have directed my attention to the possibility of making similar observations at a place within the Arctic Circle, and in particular in the region of marked auroral activity; and next autumn it is hoped to send out a group of workers from England to investigate the upper-atmospheric ionisation at Tromsö in Norway. Such work will, I think, form a suitable item for the 1932–33 International Polar Year programme.

Sept. 7, 1877.—Sir John Cadman, G.C.M.G., past president of the Institution of Mining Engineers and of the Institution of Petroleum Technologists.

After occupying the chair of mining and petroleum engineering in the University of Birmingham, and controlling the petroleum executive during the War period, I became technical director and eventually chairman of the group of companies controlled by the Anglo-Persian Oil Company. In these capacities I have been able to apply my scientific and administrative experience to the complex organisation of a great industrial concern in which there existed a maximum opportunity for the application of science to industry.

I have given particular attention to the application of geophysics to geological work, of improved chemical and physical methods to the treatment of petroleum, to the elaboration of new oil products, and to the hydrogenation of coal and oils. The problem which is particularly engaging my attention at present relates to the balancing of the world's fuel supplies, having regard to their relative physical availability and the relevant economic factors.

Sept. 9, 1867.—Dr. Robert Mond, president of the Faraday Society and of the Egypt Exploration Society, honorary secretary of the Davy Faraday Research Laboratory, joint treasurer of the Palestine Exploration Fund and treasurer of the British School of Archæology at Jerusalem, and honorary trustee of the Royal Ontario Museum.

I am engaged in assisting astronomical, chemical, medical, agricultural, archæological, and prehistoric research in England, Egypt, Palestine, and Brittany, as well as keeping in touch with general scientific and technical progress.

Problems which are worthy of investigation are: (1) Preventive inoculation of cows against tuberculosis. (2) Production of clean, cool, raw milk of a quality fit for conversion to human food (specialised feeding of cows). (3) Methods of modification of such milk to suit individuals.

Subjects to which I have given attention and which require further elucidation are: (1) Study of rotary gas engines. (2) Alloys. (3) The time-lag between wholesale and retail prices.

Sept. 12, 1851.—Sir Arthur Schuster, F.R.S., formerly secretary (1912–19) and foreign secretary (1920–24) of the Royal Society; honorary professor of physics in the University of Manchester.

Old age and failing health prevent my taking any further active part in scientific investigation; but the reminiscences of a long life, which I am collecting, may direct attention to matters of scientific interest.

Societies and Academies.

Paris.

Academy of Sciences, July 6.—**R. Fosse, A. Brunel, and P. E. Thomas**: The application of the quantitative spectrophotometric analysis of allantoin to the blood of some mammals and to the seed of numerous plants. Figures are given for the allantoin found in the blood of some mammals and in a large variety of seeds. Two seeds are remarkable for the high proportion of allantoin they contain, *Phaseolus mungo* (0·18 per cent) and *Dolichos sinensis* (0·33 per cent).—**L. Cayeux**: The existence of organic residues and especially of verticiliate siphon Algæ in the limestone schist system of the Belgian Congo.—**S. Stoïlow**: The values of the analytical functions in the neighbourhood of the boundary of a domain of regularity.—**M. Fekete**: Suites of factors retaining the class of a Fourier's series and also of certain local individual properties of the corresponding function.—**Laurent and Augustin Seguin and André Labarthe**: An apparatus for the study of the phenomena of injection and of combustion in motors by the ultra-cinematograph. By means of a special arrangement of a neon tube and condensers, the apparatus described can take up to 100 photographs at the rate of 30,000 per second.—**Pan Tcheng Kao**: The velocity of propagation of aerial ultra-sound waves. A study of the velocity of propagation of ultra-sounds by Pierce's method.—**Ch. Dietsch**: A method of measuring high intensities of continuous current.—**Edouard Belin**: The secrecy of telegraphic and radiotelegraphic transmissions. The message is transmitted in its original form (telephotography or teleautography) and distorted by a special machine before transmission. At the receiving end is a similar machine worked the reverse way.—**G. Mahoux**: The influence of electromagnetic waves on the resistance and hardness of metals and alloys.—**Mme. M. Châtelet-Lavollay**: The comparative absorption spectra of complex salts of chromium and of trivalent cobalt.—**C. Marie and N. Thon**: The phenomena of expansion presented by certain electrolytic deposits of metals. The experimental method is based on the direct observation of the deformations undergone by a thin flexible cathode, one side of which is covered with an insulating material. Metallic deposits have a general tendency either to contract or dilate. The results vary with the conditions (nature of the solution, acidity, nature of the cathode, state of the surface, and so on) and have a practical interest from the point of view of the adherence of deposits and their defects.—**Mme. P. Curie and S. Rosenblum**: The magnetic spectra of the α-rays of the active deposit of actinon.—**A. Bates**: Temper and ageing of extra-mild steels.—**W. Broniewski and J. Król**: The cold hardening of iron.—**A. Michel-Lévy and H. Muraour**: The temperature of deflagration of colloidal (explosive) powders. In order to ensure identity of temperature of explosive and surroundings, the tests were made on shavings weighing from 1 mgm. to 2 mgm. For more than 150 explosives examined the deflagration temperature was round about 200° C. and not 170° as generally accepted.—**Grégoire**: The number of pairs of ions produced in air by an α-ray of polonium.—**Augustin Boutaric and Jean Bouchard**: The influence of light on the flocculation of colloidal solutions in a fluorescent medium. Rôle of coloured inhibitors and of the viscosity of the medium.—**Marcel Ballay**: Some properties of austentitic grey cast irons.—**M. and Mme. M. Lemarchands**: Concerning chemical inertia.—**J. J. Rutgers**: Modification of Pregl's method for determining nitrogen. The changes suggested are mainly directed towards reducing the time required for the determination.—**A. Sanfourche and A. Portevin**: The attack of various alloys by phosphoric acid solutions.—**P. Brenans** and **B. Rapilly**: Mercury salicylate.—**L. Debucquet** and **L. Velluz**: Organic compounds of tungsten and molybdenum containing sulphur. These metals form double sulphides with piperazine and piperidine: these are crystalline substances of definite composition.—**A. Mailhe** and **Creusot**: The transformation of benzene into methane. A quantitative study of the production of methane from a mixture of benzene and hydrogen in presence of reduced nickel as catalyst. Much higher yields of methane were obtained with benzene carefully freed from thiophene.—**Charles Dufraisse** and **Marius Badoche**: Researches on the dissociable organic oxides. Dihydroxy-dihydrorubrene, $C_{42}H_{28}(OH)_2$, a fourth product of oxidation reducible to rubrene.—**Yves Milon**: The evolution of the coast-line and the formation of tombolos in the Paimpol region (Côtes-du-Nord).—**François Ruellan**: The decomposition and disaggregation of the biotite granites in Japan and Corea and the resulting forms.—**Caulle** and **Idrac**: The phenomena of the whistling pits near Caux.—**M. Bridel** and **R. Lavieille**: The sweet principle of Kaá-hé-é (*Stevia Rebaudiana*). The products of diastase hydrolysis of stevioside; glucose and steviol.—**Pierre Chouard**: Specific correlations proved for some Portuguese Scilla (*Scilla monophyllos*, *S. Ramburei*, *S. odorata*).—**Emery**: Bacterial origin of the tumours of the elm. These tumours are proved to be of bacterial origin. They are caused by *Bacterium tumefaciens*. This organism has been isolated by the author from one of the tumours, and the process of invasion has been reproduced experimentally on another young elm.—**L. Lavauden**: A new *Propithecus* (*Propithecus Perrieri*) of Madagascar.—**E. Le Breton**, **F. Mocoroa**, and **E. Stulz**: The proteolytic ferments of the intestinal juice and of the pancreatic juice. It is concluded that only abnormal pancreatic juices contain ereptic ferments or kinase, or sometimes both. Independently of any kinase of pancreatic origin, the intestinal juice always contains ereptic ferments and enterokinase.—**Albert Leulier** and **Mme. Andrée Roche**: The mechanism of the antiglycosuric action of santonine. From the therapeutic point of view, santonine ought to be a useful adjunct to insulin in the treatment of certain forms of diabetes.—**Maurice Piettre** and **Boris Celan**: The formation of articular humours of fibrin apart from the fibrinogen of blood origin. The function of the white cells.—**Mme. J. Kostitzine**: The statistics of the infestation of hermit crabs by *Chlorogaster*.—**Néda Marinesco**: The electromotive force of filtration produced by the ascent of the sap in plants. It has been shown that it is possible to make the sap rise or fall more or less rapidly in plants by applying a potential difference to the stems. The results afford an explanation of the results obtained by acting with a high frequency field on some plant species.—**Jean Troisier** and **Roger Cattan**: Exanthematic fever in man, without visible symptoms, caused by *Rhipicephalus sanguineus*, its virulence for the ape and guinea-pig. A man inoculated with crushed *Rhipicephalus* showed no symptoms of the disease, but his blood was virulent to an ape (*Cercopithecus Patas*). A guinea-pig was also infected by the blood. The inoculated man, although showing neither fever nor eruption, gave a positive Weil-Felix reaction.—**Félix Bertyn**: The poisonous effect of the fogs of the Meuse valley is due to industrial emanations. The fatal effects of the fog in the Meuse valley during December 1930 have been variously attributed to the fog alone, or to this with some contamination with micro-organisms. The author puts forward evidence that neither of these hypotheses can account for the facts, and it is much more probable that the fumes from chimneys and from zinc works were responsible for the fatalities.

Leningrad.

Academy of Sciences, *Comptes Rendus*, 1931, No. 1.—**G. A. Nadson** and **G. Filippov**: The formation of new stable races of micro-organisms under the influence of X-rays. (2) Description of races of *Sporobolomyces*. New races obtained in cultures of *Sporobolomyces* under the influence of X-rays are described in detail. The races retain their morphological and physiological characteristics after hundreds of generations on different media, without exhibiting any tendency to revert to the original form. Some of the races differ from the original to such an extent that they might be considered as distinct species and even genera.—**N. F. Alexeenko**: Diatoms growing on stones on the Black Sea littoral near Sebastopol. The following species were found in large numbers: *Synegra gracilis* Kutz. var. *commutata* Grun., *Mastogloia interrupta* Hantzsch, *M. pontica* sp. n. and *Nitzschia reinhardi* sp. n. The two new species are described and figured, and comparative tables of species of *Mastogloia* and *Nitzschia* are given.—**A. Zachvatkin**: Periodic variations in the level and in the chemical composition of the water of Lake Gusinœ, Transbaikalia. Lake Gusinœ, like Lake Baikal, belongs to the system of post-Tertiary lakes. During the last two centuries the lake has sometimes been reduced to two small lakes, and then has again become very large in area. The chemical composition of the water has changed accordingly, the lake having been reported by some authors as a salt lake, while at present it contains fresh water. The fauna is very poor, which can be explained by the frequent changes in the salinity of the lake.—**A. Frank-Kamenetskii** and **V. Koncevich**: The chemical composition of the water of the hot springs in northern Transbaikalia. Twenty-seven groups of thermal springs have been investigated by the authors, who report on the chemical composition of the waters. Sodium sulphate is the main component of the water, while silicic acid and its salts are also common. The temperature of the water in different springs ranges from 32° to 80° C.—**D. Beliankin**: Anemusite (with reference to pacifites of Barth). The author, on the basis of analyses of anemusite and of pacifites, expresses the opinion that they are not basalts with anemusite, in the sense of Wright and Washington, but simply basalts with the excess of the aluminate, or aluminated basalts. The excessive aluminate is contained not only in plagioclase, but also in the pyroxene of the rock.

Washington, D.C.

National Academy of Sciences (*Proc.*, vol. 17, No. 5, May 15).—**A. L. Dryden, jr.**: Accuracy in percentage representation of heavy mineral frequencies. The present tendency is to count mineral grains in a section and express the result as a percentage. This can give higher accuracy than inspection of samples, but statistical methods indicate the importance of stating exactly how the result is obtained.—**Harvey Cushing**: (4) The method of action of pituitrin introduced into the ventricle. The characteristic effects of intraventricular injection of pituitrin are not observed when the hypothalamic nuclei are out of action.—(5) The counteractive effect of tribromethanol (avertin) on the stimulating response to pituitrin injected in the ventricle. The conclusions of the previous paper are supported by the fact that avertin, which is believed to act on centres in the diencephalon, counteracts the effect of pituitrin.—(6) Concerning a possible 'parasympathetic centre' in the diencephalon. Includes a review of the evidence of the foregoing five papers; it is suggested that the neuro-hypophysis bears a similar relation to the parasympathetic division that the adrenal medulla does to the sympathetic division of the autonomic nervous system.—**A. H. Sturtevant** and **Jack Schultz**: The inadequacy of the sub-gene hypothesis of the nature of the scute allelomorphs of *Drosophila* (see NATURE, Aug. 15, p. 273).—**L. V. Morgan**: Proof that bar changes to not-bar by unequal crossing-over.—**Chas. W. Metz** and **M. Louise Schmuck**: Differences between chromosome groups of soma and germ-line in *Sciara*. Deductions as to inheritance in *Sciara* based on chromosome counts in germ tissue require modification in view of the fact that the chromosome group for body tissue differs from that for germ tissue in both sexes.—**Myron Gordon**: The hereditary basis for melanosis in hybrids of Mexican killifishes.—**Mary Sears**: The responses of the deep-seated melanophores in the frog to adrenalin and pituitrin. The responses are similar but take place more slowly.—**Earle B. Perkins** and **Theodore Snook**: Control of pigment migration in the chromatophores of crustaceans. Pigment migration appears to be due to a substance produced by the eye-stalks and is of the nature of an interspecific hormone; the efficiency of the substance is increased by boiling the sea-water extract.—**Forrest Clements**: The correlation between tanning and unexposed skin colour as recorded by the colour top. Field studies on American Indians show high correlation between unexposed skin colour and degree of colour change by exposure; this correlation is negative for the black and red elements of the colour top and positive for the yellow and white. Thus, the darker the skin, that is, the greater the proportion of the black and red elements and the less the proportion of yellow and white, the less will be the amount of tanning on exposure. This suggests a possible exposure-index for ultra-violet light therapy.—**Henry B. Bull** and **Ross Aiken Gortner**: Studies on electrokinetic potentials (9). The electrical field of force at liquid-liquid interfaces. Salt solution is forced as a spray through a hole in one electrode and the charge carried to another electrode measured, the electrodes being immersed in oil. The curves obtained resemble closely the electrokinetic potential curves at cellulose-aqueous solution and glass-aqueous solution interfaces.—**Wilder D. Bancroft** and **G. H. Richter**: Reversible coagulation in living tissue (3). Evidence from the treatment of lunatics supporting the hypothesis that excessive dispersion or excessive coagulation of nerve colloids can cause insanity; these two forms of insanity obviously require different treatment.—**R. J. Seeger**: A critique of recent quantum theories.—**Paul S. Bauer**: Dissipative dynamical systems (1).—**B. O. Koopman**: Hamiltonian systems and transformations in Hilbert space.—**Marston Morse**: The order of vanishing of the determinant of a conjugate base.—**G. A. Miller**: Automorphisms of order 2 of an Abelian group.—**Tracy Yerkes Thomas**: On the unified field theory (6).

Diary of Societies.

TUESDAY, SEPTEMBER 8.

INSTITUTE OF MARINE ENGINEERS, at 6.—President's Address.

LONDON NATURAL HISTORY SOCIETY (Botany Section) (at London School of Hygiene and Tropical Medicine), at 6.30.—A. W. Robbins: Some Preliminary Remarks on Brambles.

QUEKETT MICROSCOPICAL CLUB (at 11 Chandos Street, W.1), at 7.

FRIDAY, SEPTEMBER 11.

INSTITUTE OF MARINE ENGINEERS (Official Visit to the Shipping, Engineering and Machinery Exhibition at Olympia). At 3.—A. C. Hardy: Marine Engineering as a Marketing Proposition. At 6.—A. R. T. Woods: The History of Marine Refrigeration.

CONGRESSES.

SEPTEMBER 1 TO 19.

INTERNATIONAL ILLUMINATION CONGRESS. (For Programme see NATURE, Aug. 29.)

SEPTEMBER 6 TO 12.

INTERNATIONAL CONGRESS FOR TESTING MATERIALS (at Zurich).

Tuesday, Sept. 8.—Dr. W. Rosenhain: Chairman's Address. (Group A.)
  J. G. Pearce: The Structure and Mechanical Properties of Cast Iron.
  Prof. E. Piwowarsky: Der Grauguss und seine Prüfmethoden.
  Prof. A. Portevin: Caractérisation des propriétés mécaniques des pièces moulées en fonte grise.
  Prof. F. Pisek. Tests on Cast Iron—A Consideration of Test Results Obtained in Czechoslovakia.
  Dr. E. Dubi. Beitrag zu der Frage der Prufungsverfahren fur Gusseisen.
  Prof. J. Galibourg: Les métaux aux temperatures élevées.
  Dr. A. Pomp and Dr. W. Enders: Abkurzungsverfahren zur Bestimmung der Dauerstandfestigkeit des Stahles.
  R. G. Batson and H. J. Tapsell: Materials at High Temperatures.

Wednesday, Sept. 9.—Prof. P. Ludwik: Ermudung.
  Dr. H. J. Gough: The Present State of Knowledge of Fatigue of Metals.
  Dr. D. J. McAdam: Fatigue.
  Dr. P. Forcella: L'essai aux chocs répétés à flexion alternée sur les rails des chemins de fer italiens; essais de torsion altérnée de 360° sur fils de cables métalliques pour voies ferrées aériennes et funiculaires.
  Dr. E. Schulz and Dr. H. Buchholtz: Über die Entwicklung der Dauerprufung in Deutschland.

Thursday, Sept. 10.—Dr. M. Moser: Der Stand der Kerbschlagproben-Frage in Deutschland.
  Prof. R. Zoja: Essais au choc sur barreaux entaillés.
  Dr. M. Schmidt: Kerbschlagproben, Normenprobe.
  Dr. R. H. Greaves: Meaning of the Notched-Bar Impact Test for Investigation and for Acceptance Test Purposes.
  A. Steccanella: L'essai de résilience comme essai de reception.

Friday, Sept. 11.—F. F. Lucas: Advances in Microscopy.
  Prof. C. Benedicks and H. Lofquist: Progress of the Knowledge regarding Slag Inclusions in Iron and Steel.
  Dr. J. L Haughton: Progress of Metallography
  Prof. W. Guertler: Die neuere Entwicklung der Konstitutionsforschung der Legierungen.
  Prof. A. Westgren: X-Ray Investigations of the Constitution of Alloys.

Tuesday, Sept. 8.—Prof. M. Roš: Chairman's Address. (Group B.)
  Prof. R. Grengg: Anwendung mineralogischer und petrographischer Erkenntnisse auf die technische Materialprufung nichtmetallischer anorganischer Stoffe.
  Prof. P. Niggli: Anwendung mineralogischer-petrographischer Erkenntnisse auf die technische Materialprufung nichtmetallischer anorganischer Stoffe.
  Prof. G. Berg: Welche petrographischen Eigenschaften sind fur die technische Eignung der Gesteine von besonderer Wichtigkeit?

Prof. H. Burchartz: Die Verfahren zur Prufung von Strassenbau- und Gleisbettungsstoffen auf Widerstandsfahigkeit gegen statische und dynamische Beanspruchungen.

J. F. Cellerier: Etude des moyens de préservation des pierres naturelles.

Prof. J. O Roos af Hjelmsäter: Chemical Action of Aggressive Waters on Cement.

Prof. G. Wiegner: Chemische Einflusse auf Zement und Beton im Boden.

Prof. I. Vandone: L'unification mondiale des essais des mortiers et des bétons de ciment

Dr. G. Haegermann: Die Zementprufung.

Dr. L. Lili: Propriétés intimes du ciment portland et de leurs conséquences.

Prof. Q. Sestini and Prof. L Santarelli: Le fer dans la constitution des ciments et les ciments ferreux.

C. Vigliani: Comportement des ciments naturels et artificiels après de longs délais.

Dr. A. Perfetti and Dr. E. Palumbo: Influence des variations de température des ambiants de préparation et de conservation des éprouvettes de mortier normal sur leur résistance mécanique.

Dr. A. Perfetti: Influence de la quantité d'eau de gâchage sur la résistance des mortiers normaux de ciment aux essais mécaniques.

Prof. F. Klokner: Rapport entre la ténacite et la résistance des différentes sortes de ciment.

A. Maitre-Devallon: Détermination du dosage des mortiers et betons en ciment ou chaux hydraulique.

Wednesday, Sept. 9.—Prof. R. Grun: Zemente mit hydraulischen Zuschlagen.

Prof. F. Ferrari: Ciments et substances pouzzolaniques.

Dr. C. Vittori: Les ciments pouzzolaniques rationnels de Segni.

B. L. Katzigheras: Einige Ergebnisse von Untersuchungen mit Santorinerde.

Dr. E Rengade: Les ciments alumineux.

P. H. Bates: Suggested Investigations of High Alumina Cements.

Thursday, Sept. 10.—A. Pena Bœuf: Élasticité et résistance des bétons.

Prof. O. Graf: Über die wichtigsten Eigenschaften des Betons, uber ihre praktische Bedeutung und uber die Nutzbarmachung der Erkenntnisse.

Prof. L Santarella: Résistance et élasticité du béton.

Prof. W. A Slater: Designing Concrete for High Strength, Low Permeability, and Low Shrinkage.

Friday, Sept. 11.—Prof W. Gehler: Festigkeit, Elastizitat und Schwinden von Eisenbeton.

Prof. F E. Richart: Stresses and Strains in Reinforced Concrete Columns.

Dr. F. Emperger: Die Stauchungsfahigkeit des Betons.

Prof. J. A. Bakker: L'état des constructions en béton armé âgées de 20 ans et plus.

Tuesday, Sept. 8.—Prof. J. O. Roos: Chairman's Address. (Group C.)

Prof. H. Suida and W. Janisch: Asphalte und Bitumen. Eignung im Bau- und Strassenbauwesen.

P. Hubbard and C. S. Reeve: Methods of Tests or Bituminous Materials.

Dr. J. P. Pfeiffer.—Summary of Investigations made in Holland and her Colonies with Respect to the Description of the Identification of Woods, with a View to drawing up a Method applicable in Practice.

R. Schlyter: Researches into Durability and Strength Properties of Swedish Coniferous Timber.

Wednesday, Sept. 9.—C. J. Chaplain: The Development of Mechanical Testing of Timber in Great Britain with a Note on Preservative Treatments.

M. L. Monnin: Essai des bois.

Dr. A. Perfetti: Étude des caractéristiques mécaniques de quelques qualités de bois.

Prof. E. Casati: Essais comparés sur éprouvettes de dimensions différentes de quelques essences de bois.

Prof. K. Ryska. Einige Fragen aus dem Gebiete der technischen Prufungsmethoden fur Hölzer.

Prof. M. Roš and Dr. J. Brunner: Die Knickfestigkeit der Bauholzer.

Thursday, Sept. 10.—Dr M. van Rysselberge: Le vieillissement artificiel des huiles minérales spéciales.

Prof. F. Frank: Alterung organischer Stoffe, wie Kautschuk, Öle, Harze, Fasern usw.

Dr. G. Barr: Ageing of Organic Materials.

Dr H. Stager: Die Alterung organischer Werkstoffe.

Dr. C. H. Weiss and P. Woog: Unification de la désignation de la viscosité. Nécessité d'employer le coefficient de viscosité absolu statique ou le coefficient de viscosité absolu cinématique pour la mesure pratique de la viscosité.

Friday, Sept. 11.—Prof. K. Bunte: Probenahme von Kohlen, Koks und anderen Brennstoffen, sowie von Schlacken und Aschen.

Dr. E. S. Grumell and Dr. J. G. King: The Sampling of Coal and Coke.

W. A. Selvig: Sampling Coal.

Dr. F. S. Sinnatt: The Determination of the Fusion Point of Coal Ash.

Prof. K. Bunte: Methoden zur Bestimmung des Schmelzverfahrens der Asche.

Dr. R de Benedetti and Dr. G. Rossi: Détermination des matières volatiles dans les combustibles solides.

Prof. P. Schläpfer: Untersuchungsmethoden zur Bestimmung des Back- und Blahvermogens und des Treibdruckes von Steinkohlen.

Monday, Sept. 7.—Prof. W. v Moellendorff: Chairman's Address. (Group D.)

L R. Feret: La grosseur des grains des matières pulvérulentes.

Prof. A. H M. Andreasen: Theoretisches und experimentelles uber Korngrosse und Feinheit.

Vanishing Life of Australia.

THE conditions which made for the evolution of the fauna of Australia along its unique path, the isolation of the continent associated with the early influx of primitive groups of animals, are now hastening that peculiar fauna towards its doom. Uniqueness has its own attractions, and there can be no replenishment of the disappearing forms from the outside world. There can be no doubt on the question of the disappearance of Australian birds and mammals. Sir James Barrett expresses the general opinion in Australia when he says: "The answer is unequivocal. Except in certain places where enlightened citizens have protected them, they are all disappearing. It is difficult for anyone to show a visitor in the State of Victoria the larger marsupials or the lyre bird. It is quite impossible to find the smaller marsupials except in a few favoured places and with great trouble. It is, indeed, feared that some varieties have been exterminated."

The same opinion is held in America. The title of our article is that of a paragraph in the Annual Report for 1921 of the American Museum of Natural History, which goes on to say: "We are approaching the close of the age of mammals all over the world, but in no continent has the devastation been more rapid than that of Australia, owing to three causes: deforestation, an enormous fur trade, and an increasing leather trade. In 1921 it became apparent that the American Museum must secure its representative collection now or never. Accordingly an expedition headed by Curator William K. Gregory was sent to Australia . . . to explain the chief purposes of the Museum, which are to secure an exhibition of the wonderful and unique life of Australia, past and present, as distinguished from a research collection, which belongs properly in the Australian museums and in the great British Museum of Natural History in London."

It is a rule in the decline of a fauna that when agriculture and commercial slaughter have reduced numbers to rarity, new forces step in to complete the destruction. The rare animal becomes desirable, scientifically and commercially, and collectors, animated by one enthusiasm or the other, rush to secure the last of the specimens. In the British Isles with their limited fauna this tendency has been particularly forced upon the notice of naturalists. A few years ago, the once common kite, in spite of strenuous protection, was reduced to some five breeding pairs on the borders of

Wales; the great skua and the St. Kilda wren were brought to the verge of extinction, the osprey was exterminated, all through the activities of collectors.

In Australia the same forces have taken a hand in the threatening final stages. Sir James Barrett, in the work from which we have already quoted ("Save Australia", 1925, p. 3), says: "Australia has lately been inundated with collecting expeditions, and what is still more serious, private commercial collectors are trying to obtain specimens before extermination takes place"; and Dr. J. A. Leach writes (p. 122): "The rumour having gone forth that the Australian mammals, the most primitive in the world, are doomed to early extinction, the museums of the world are making special efforts to obtain specimens of Australian animals before it is too late. Many scientific expeditions have visited Australia in recent years. These must be controlled. Worse still, prices for Australian birds have soared so high that the greed of private traders has been excited, and some big shipments have been sent from Australia for private gain. The mortality has been heavy, and the cruelty involved great, but the high prices obtained for the remainder have yielded a handsome profit."

We had these facts and opinions in mind when in a note (July 11, p. 63) we referred to a new collecting expedition to Australia from the Harvard Museum of Comparative Zoology. Prof. T. Barbour, director of that museum, and himself a distinguished naturalist, takes exception to our comment, which he thinks may be interpreted as expressing jealousy of American scientific activity. We need scarcely assure him that our only jealousy is for the safety of the rare animals of Australia, and we welcome his assurance that no attempt is to be made to secure 'long series', although that was scarcely apparent from the American notice of the expedition, which stated that the collection aimed at being one of the largest and best balanced in the world. The instructions given to the members of the expedition in connexion with their collecting, as stated by Prof. Barbour, are unexceptionable, and we are certain that Harvard will make good scientific use of the specimens collected. Indeed, it becomes clear, when we examine the staff of this expedition and of the Agassiz Museum, from which it emanates, that this is no collecting expedition but one with more serious and desirable scientific aims.

Museums of zoology a century ago were collections of animals similar to and about as informative as other indiscriminate collections. Then in Darwinian times an attempt was made to illustrate the main lines of evolution, and following this to obtain long series of animals to study the variation of the individual species, so as the better to understand this evolution. The mere student or sightseer was relatively little catered for, and the bewildering variety of animals in the museum cases depressed him. To-day the adequate display of properly labelled and well selected animals illustrative of the phyla and their subdivisions is recognised as of peculiar necessity to students, since they have to learn much of this side of zoology, and also of the possible lines of evolution, without the aid of teaching that has to be thrown more and more in the direction of experimentation and the study of the forms of life in relation to their surroundings. It is this last side, which we may term the natural history of animals, that is likely to be increasingly occupying the attention of museums, for it interests the public also. To prepare the requisite displays, even of common animals, requires that each curator must know intimately his forms of life in the field, together with the vegetation and other animals associated with them. We understand that this is so well recognised at the Agassiz Museum that its staff is dispersed into the field during the summer months; the local province here is North America, including the West Indies. Occasional expeditions travel farther afield, following out the practice of Louis Agassiz, but no longer restricting themselves to marine life. The present expedition is under W. M. Wheeler, the distinguished American entomologist, whose studies on social and other insects have materially guided the development of modern research on insect life.

So far as we can see, it appears doubtful whether both the terms 'scientific' and 'collecting' can be applied to any expedition. The collecting expedition requires action and often a personnel not altogether desirable, while it tends to think too much of the value, as instanced by rarity, of the specimens obtained. The scientific expedition is necessarily led by experienced naturalists, whose study is the actions of the various forms of life in their natural habitats, and whose collections are supplementary to the understanding of these. These men personally dislike to kill, and no expedition led by them will ever gauge its success by the 'bag'. Such expeditions should be encouraged, whatever may be their origins, since their sole aim is to add to the common stock of knowledge.

This, however, leaves the question of the preservation of the fauna, which usually means the birds and mammals, of Australia and other regions unconsidered. It is surely useless to obstruct even 'collecting' expeditions, while the local fur and feather merchants and the professional collectors are left to pursue their aims. We suggest that nothing except local legislation, honestly and firmly applied, can really be effective in any country. The birds, mammals, and other animals can be classified by their rarity and by their effects, beneficial or otherwise, in relation to man. The introduction of animals from other countries would be considered as affecting both the local indigenous fauna and man's agriculture. In addition, national parks might be established, as has been done in Africa and other countries, and there are surely large tracts of Australia and Tasmania which might be so declared without seriously affecting the local population. Sporting, collecting, and scientific expeditions would be either licensed or prohibited as might seem desirable. There would be no hardship in this, for science has nothing to fear when it is understood that the progress of the State is inseparably locked with its own.

Geophysical Prospecting.

The Principles and Practice of Geophysical Prospecting: being the Report of the Imperial Geophysical Experimental Survey. Edited by A. B. Broughton Edge and Prof. T. H. Laby. Pp. xiii + 372. (Cambridge: At the University Press, 1931.) 15*s.* net.

TO the Imperial Geophysical Experimental Survey, 1927–29, was entrusted the task of testing, under conditions and on problems available in Australia, the applicability of the principal methods—gravitational, magnetic, seismic, and electrical—which recent developments in apparatus for local geophysical investigations have placed at the disposal of the economic geologist. As explained by the Director in his introduction to this Report, special stress was placed on the electrical methods, in view of the paucity of reliable information regarding these methods which was available at the time when the Survey was initiated.

The volume, however, comprises a good deal more than a mere detailed account of the tests undertaken in Australia, valuable though these are. As the title hints, it is, in addition, a comprehensive review of the principles of applied geophysics, and as such immediately stands out as the best available English exposition of these principles. Moreover, in the wealth of detail and illustration used to describe the apparatus employed, and the invaluable accounts of the procedure used in the field and in interpreting the results, the book fulfils all the functions of a practical manual of the science. Finally, in the comprehensively illustrated reports of the actual surveys undertaken, with the careful analysis and conclusions added both individually and as a whole, the volume permits all interested in the economic application of geophysics to form conclusions regarding its value on problems differing widely in characteristics. Of very particular interest in this connexion is the frequency with which, so far as possible, several methods have been tested on the same problem, in order that a comprehensive estimate of costs and value might be made.

The work is ingeniously divided into two parts. The first part, occupying some two-thirds of the book, may be regarded as the report proper; the second part comprises a very detailed exposition of the theory of each method and the apparatus employed. Thus the first part is more suited to the mining engineer and geologist who wish to assess the value of the method and its characteristic scope, whilst the second part is more adapted to the critical analysis of the physicist. In each chapter of Part 1, a brief introduction to the method is imparted, but much greater detail of the physical principles involved will be found in Part 2.

In Chapter xi will be found the general conclusions as to the applicability of the methods in Australia, and hints and statistics to serve as a basis for judgment as to their value elsewhere, but certain conclusions are also drawn in the various chapters of Part 1. Each section of the volume, whether principles, apparatus, procedure, or actual surveys, aims at a high standard, and attains it within the necessary limitations of the book. It is doubtful whether the whole range of the principles and procedure of geophysical prospecting could be comprehensively surveyed in a single volume of reasonable dimensions. So much of both pure and applied physics is involved in each individual method that a good-sized book could readily be filled in each case, as indeed has been demonstrated by the German publication "Sammlung geophysikalischer Schriften".

In the present volume, the tendency has been to build the 'procedure' round the actual 'practice' in Australia, so that in certain respects the account is simplified. On the other hand, the particular problems selected for the trial of some of the methods, for example, the gravitational, whilst probably representing the best available in Australia, by no means covered the complete field of applicability of these methods. Consequently the procedure adopted in these instances was rather restricted, and the exposition in these methods may be regarded as somewhat elementary. Similarly, the descriptions of the instruments used, and the conclusions derived as to the scope of these particular methods, are limited by the relatively restricted work carried out in Australia.

The above criticism applies generally to the gravitational, magnetic, and seismic sections, but they are nevertheless excellent outlines of principles, procedure, and apparatus. In the case of the electrical methods, the exposition is in all respects more comprehensive and complete. The whole field of direct current, low and high frequency alternating current supplies, potential, resistivity, and phase measurements, conductive and inductive excitation of the earth—in fact, practically all the known varieties of method used—are surveyed conscientiously and efficiently. It is in this section that the chief value of the volume lies. The accounts of electrical apparatus are very detailed and contain descriptions hitherto unavailable. In addition, in the method known by the name 'Potential-Ratio', we find a distinct advance in procedure of great importance. Even here, however, certain recognised methods were not actually tested in Australia and are not dealt with. One such method is that associated with the name of Gella, of the Elbof Company. In this method the measurements of the electromagnetic field, due to a current field introduced by two electrodes sited very near each other, are made in the region beyond the electrode interval, and certain advantages are claimed for such a procedure. As the Elbof Company has been operating under a commercial contract in Australia, it is unfortunate that no opportunity arose for the Survey to test the claims of this particular method. Two other methods, one involving the use of very low frequencies—for example, about 50 to 100 cycles—and the other utilising the electromagnetic field in the neighbourhood of a single rectilinear cable—are of comparatively recent development and therefore were not available for test during the Australian survey work.

Whilst the above reflections may serve to indicate how the volume falls somewhat short of the ideal of a really comprehensive account of the principles and practice of geophysical surveying, we would hasten to affirm that it is exceptionally complete. The very numerous diagrams and photographs are of immense value to the student, and to the practising geophysicist.

Turning now to the accounts of the various surveys, unqualified approval may be expressed of the way in which these have been presented. The selection of the tests gave a wide variety of problems, including the location and definition of deposits of sulphide and other ores, brown coal, and graphite, and the determination of regions bearing saline water. The accounts of the surveys are copiously illustrated by admirably clear maps and sketches, and many folding plates are inserted. The descriptions of the procedure, analysis, and interpretation are models of what such accounts should be, and are in striking contrast to the vague, unintelligible travesties which we meet so frequently in the average description of electrical surveys undertaken by commercial concerns. We do not encounter here the usual hieroglyphic indication of a 'good conductor', which has no apparent connexion with the actual measurements, but contrives to present a specious concordance with the actual mineral deposits known to exist by borings. In this volume, the whole procedure of the trial is made perfectly clear and the method of interpretation rendered intelligible. There is no attempt to gloss over difficulties or to hide perplexities. Finally, so far as was known by the date of publication, the results of confirmatory drillings are given. Unfortunately, the close of the Survey coincided with the advent of intense depression in Australia, so that few of the valuable indications obtained by the Survey have as yet been prosecuted by drilling or mining. This will doubtless be remedied as future opportunity arises. Meanwhile, it is heartening to note that many successes are already confirmed, in some cases where valuable deposits were previously unsuspected.

We cordially recommend this volume to the attention of all interested in economic geology and mineral resources generally, and, above all, to students and exponents of geophysical prospecting. The remarkably low price of the work is a mystery; we hope it will not create in the mind of the would-be purchaser the erroneous impression that it has any relation to the value. Had this book been published in Germany or the United States it would be twice the price.

Treatise on Physical Chemistry.

A Treatise on Physical Chemistry: a Co-operative Effort by a Group of Physical Chemists. Edited by Prof. Hugh S. Taylor. Second edition. In 2 volumes. Vol. 1. Pp. xv + 852 + 48. Vol. 2. Pp. xii + 901-1766 + 48. (London: Macmillan and Co., Ltd., 1931.) 30*s.* net each vol.

THE welcome appearance of a second edition of this two-volume treatise on physical chemistry has clearly demonstrated both the practicability and the usefulness of Prof. Taylor's somewhat novel experiment of attempting to produce a text-book by the co-operative efforts of different individuals; a practice usually reserved for dictionaries and tomes of a more encyclopædic character. Whilst the first edition was a good treatise, this second edition is better. Apart from the inclusion of new matter and the adjustment of stress on importance of what may be termed personal factors in the various chapters, the volumes, on the whole, are much more evenly balanced. We note, for example, the growth of uniformity in the treatment of the theory of solutions and of reactions taking place therein, a more minute analysis of the problems of the kinetic theory of gases, and a very desirable extension of the treatment of colloidal systems. Dr. Dushman's chapter on the quantum theory and atomic structure is really a remarkable production both for clarity and scope.

In the introduction to the first edition, Prof. Taylor states that the first volume represents that portion of the subject which can with advantage be addressed to the first-year student; the second volume presumably to those who are spending the two subsequent years in the study of chemistry. The treatise has swollen unavoidably from 1359 to 1766 pages. To those who were brought up with Ostwald, Nernst, or Sir James Walker's books on physical chemistry as texts during their years at college, these new editions, whilst representing faithfully the growth and, as some of us like to believe, the growing importance of the subject, will be welcomed and give much pleasure; but at the same time it raises in a somewhat pertinent form the important question as to what courses in college chemistry should and what such courses can do. It would be surprising if any student on graduation in chemistry could be really *au fait* with the content of these volumes. At the same time, it is doubtful if even the clear appreciation of what are somewhat vaguely termed general principles will suffice to render a man a competent scientific worker when he leaves college. Some happy combination of general principles, the working out of examples, and development of a logical and critical faculty seem to be desirable in any college course. Such are not obtainable in treatises. For example, the first-year college student in reading the first volume would receive his first introduction to the ionic theory in the heat of hydration of gaseous ions and the Donnan distribution on the two sides of a semi-permeable membrane.

For the research student, however, the two new volumes are really excellent. It is natural that with the rapid growth of particular phases of the subject even in the new volumes certain statements require revision, for example, the sections devoted to consideration of heats of adsorption of gases on active metal surfaces. Whilst a certain amount of duplication of material is unavoidable, the proof readings must have been no light undertaking and the final text is remarkably free from typographical errors. We note a few, such as 'Seminoff' for 'Semenoff' p. 1012, 'rom' for 'from' p. 1092, and 'corresponcence' for 'correspondence' p. 1172. It is to be hoped that when the third edition is called for, Prof. Taylor will continue to adopt the policy of attempting to make the book a representation of the science as it is, and not delimit it for the purpose of providing first-year college students with material for study. I suspect that this material is already too indigestible for their consumption. The printing and binding of the volumes are excellent.

ERIC K. RIDEAL.

The Complete Evolutionist.

L'Ologénèse: nouvelle théorie de l'évolution et de la distribution géographique des êtres vivants. Par Prof. Daniel Rosa. Adapté de l'italien par l'auteur. (Bibliothèque de Philosophie contemporaine.) Pp. xii + 368. (Paris: Félix Alcan, 1931.) 35 francs.

SOME time ago there was reviewed in these pages (NATURE, May 11, 1929, p. 709) a book in which Dr. George Montandon of Paris sought to explain the origin of human races by applying a theory of evolution which had been first propounded by Prof. Daniel Rosa of Modena in 1909. Dr. Montandon's advocacy has stimulated an interest in this new theory, with the result that Prof. Rosa has translated his chief work ("Ologenesi: Nuova teoria dell' evoluzione e della distribuzione geografica dei viventi." 1918) into French. The book in its French dress is much more than a translation of the original; the author has taken the opportunity of amplifying his theory and of introducing new evidence.

Prof. Rosa claims that his theory of hologenesis gives a more complete and satisfying explanation of all the facts known to students of the evolution of living things than any other. By applying it, the naturalist is given, so he believes, an acceptable explanation of how the present flora and fauna have come into existence; the palæontologist obtains from it a clue to the distribution of species in space and time, and it solves all problems of embryology, heredity, anatomy, classification, and of adaptation. The theory of hologenesis succeeds in doing so much because of its blunderbuss charge. Its shot has been culled from Lamarck, Darwin, de Vries, Weismann, Naegeli, etc., whereto Prof. Rosa has added a potent factor of his own. His theory has much in common with that held by the late Dr. William Bateson, namely, that evolution is an unfolding of potentialities inherent in the germ plasm of the originals of living things.

To make his theory clear to his readers, Prof. Rosa uses as a simile the development of a chick from the egg. The sequence of developmental processes which give rise to the chick lie dormant in the fertilised egg, and, in the period of incubation, the potentialities unfold themselves to produce a chick. In like manner, he holds that in every species of living thing, just as in every fertilised egg, there is a load of potentialities or determinants, which, when unfolded or spent, the species reaches maturity. Having reached maturation, the germ plasm of the species undergoes a sudden change whereby the mother species suddenly gives rise to two daughter species, which differ from each other and also from the mother. The daughter species then set out to unfold their determinants, and if the environment is favourable —for environment and selection play their part in the theory of hologenesis—then maturation stages are again reached and a further dichotomy with the production of new species takes place. Given living matter laden with an infinite and suitable supply of determinants, the hologenist is armed for all the eventualities with which the living world is likely to present him.

The theory of evolution has now reached a strange stage in its progress—a stage of indifference. Biologists of all shades of opinion are convinced that living things have evolved from simpler and older forms, but for the meantime they have lost interest in how the transformation has been effected; they are careless of theories and hungry for new facts. This mood will militate against the theory of hologenesis receiving the attention it deserves, for Prof. Rosa has cast his net widely and brought up for consideration a great assortment of biological facts. He is right when he declares that no theory of evolution can be finally acceptable unless it explains by natural and observable processes the wonderful adaptations and contrivances which are to be found everywhere in the kingdom of life. He faces the problems of adaptation and seeks for an explanation by postulating that the 'determinants' must be functional in their constitution, that their unfolding must take place as a harmonious specialisation of labour. We may grant that much and yet be no nearer to an understanding of how this specialisation does take place.

Prof. Rosa's book will serve to remind its readers how far we are yet from an exact knowledge of the machinery which underlies evolution. It is the physiologist rather than the morphologist who is most likely to find the clues to the essential problem of evolution. A. K.

Short Reviews.

Foundations of Geometry and Induction. By Jean Nicod. Containing Geometry in the Sensible World, and The Logical Problem of Induction. Translated by Philip Paul Wiener. (International Library of Psychology, Philosophy and Scientific Method.) Pp. iv + 286. (London: Kegan Paul and Co., Ltd.; New York: Harcourt, Brace and Co., 1929.) 16*s*. net.

THOSE who knew the late Jean Nicod will be glad to have this translation of his two main works; yet the book itself will interest a much larger circle of readers, because of the very problems it discusses and because of the original and valuable contributions made by the author towards their solution. In discussing "Geometry in the Sensible World", Nicod starts from data of perception and tries to derive the various geometries that can be built on them, a method which is quite the inverse of Prof. Whitehead's 'extensive abstraction'. For the logical development of this very interesting method, the author shows us an animal which is endowed successively with more and more complex senses, and tries to build up gradually the geometrical world of his sensations. He obtains in this way some remarkable conclusions which strengthen the case against Kantian philosophy, and illustrate to the full the relations between symbolic logic and experience. Indeed, the line of approach suggested by Nicod is one which ought to become classical in the investigation of the problems concerning mathematics and the external world.

In the second part of this volume, "The Logical Problem of Induction" is analysed in itself and in relation to the doctrine of probability. Nicod tries to show why induction by simple enumeration is a fundamental mode of proof, and that all those who have thought they can do without it have done so only by the aid of sophisms; also, that it can increase the probability of a hypothesis, even when the new facts observed should do nothing but repeat without variation facts already known. The author endeavours, finally, to show that it is not actually demonstrated by any procedure whatsoever how inductive reasoning can raise the probability of a law to the point of indefinite proximity to a certainty. The penetrating analysis of these various theses would have no doubt led the author to a more positive construction, but his premature death has unfortunately terminated a career which would have been a credit to scientific philosophy. T. G.

School Certificate Magnetism and Electricity. By Dr. Harold Toms. (Pitman's School Certificate Series.) Pp. viii + 440. (London: Sir Isaac Pitman and Sons, Ltd., 1930.) 5*s*.

THE author justifies the appearance of this new text-book in a preface, where it is stated that the traditional division of the subject into magnetism and voltaic and static electricity has not been adhered to, and that an effort has been made to present the facts as one homogeneous and inter-related set of phenomena rather than as three vaguely connected subjects. Emphasis is laid on mechanics and units since experience has shown that " only those who realise that mechanics can be applied to electrical and magnetic phenomena ever acquire a thorough grasp of the subject". The object has been " to provide a solid groundwork for those who, at a later stage, intend taking an advanced course ".

The exposition is clear rather than detailed, and, in spite of the size of the book, is in some respects superficial. A chapter on magnetic theory is entirely devoted to Weber's theory, and gives the impression that magnetism is a simple matter, wholly understood, and presenting no difficulties. One feels that even an elementary book should direct some attention to the great strides made on the theoretical side in recent years. Alternating currents, the dynamo and accumulators, are very briefly dismissed; hysteresis and the nickel cell are not mentioned. N. M. BLIGH.

The Laboratory Mouse: its Origin, Heredity and Culture. By Dr. Clyde E. Keeler. Pp. viii + 81. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1931.)

IN this monograph, by the author of a series of papers on inherited abnormalities, especially of the retina, in the mouse, the early chapters deal with the systematic position and history of house and domesticated mice. There is much curious information: we learn, for example, that, according to the London Pharmacopœia of 1667, " A flead mouse dried and beaten to powder, and given at a time, helps such as have Diabetes "; that a special word for the dominant spotted variety of mouse appears in the earliest Chinese lexicon, written 1100 B.C.; and that " The clergy of the Middle Ages never ceased to comment upon the libidinous habits of mice. Indeed, mice were frequently raised by curious churchmen in order to observe their wicked actions ".

The origins of the different fancy breeds are traced out so far as possible. A chapter follows, cataloguing and tabulating the various gene-mutations that are known in mice, with full descriptions of their effects; this leads up to an account of heredity, normal and abnormal. A chapter on the technique of breeding and keeping mice, five pages of photographs of different varieties, and a bibliography of 184 titles conclude a very admirable little volume. G. P. W.

The Bacteriophage and its Clinical Applications. By Prof. F. d'Herelle. Translated by Prof. George H. Smith. Pp. viii + 254. (London: Baillière, Tindall and Cox, 1930.) 18*s*. net.

THIS book, based upon the Lane Lectures delivered by the author at Stanford University, California, in 1928, is addressed primarily to practitioners of medicine. The subject of bacteriophagy is a complicated one, and still in an imperfectly understood state. The history of its discovery, its nature, and its relationship to bacterial mutations, infectious diseases, and recovery and immunity, are outlined quite clearly and simply. It is not within the scope of a book of this sort to enter exhaustively into the conflicting theories of the nature of the bacteriophage, nor does it do so. The author's views as opposed to those of Bordet and his followers are given in some detail. About sixty-five pages are devoted to the clinical application of the bacteriophage. Records of its use in enteric infections, infections due to pyogenic cocci, streptococcus, and bubonic plague are included.

The book is interesting. But it is unjustifiable to conclude, as its author does, that in bacteriophage lies an explanation of all immunity to the exclusion of generally accepted theories. The clinical application is as yet far from being established.

Handbuch der biologischen Arbeitsmethoden. Herausgegeben von Prof. Dr. Emil Abderhalden. Lieferung 346. Abt. 9: *Methoden der Erforschung der Leistungen des tierischen Organismus,* Teil 7, Heft 1. *Methoden der Tierhaltung und Tierzuchtung.* Pp. 226. (Berlin und Wien: Urban und Schwarzenberg, 1931.) 13 gold marks.

THE present section of this work contains four articles on the following subjects: (1) the collection, study, and rearing of tardigrades, by Prof. Marcus, of Berlin; (2) and (3) the collection, rearing, and investigation of ticks and of fleas, by Prof. Pawlowsky, of Leningrad, two valuable articles, stressing, as might be expected, the pathological significance of the parasites; and (4) methods of investigating subterranean faunæ, by Prof. Chappui, of Klausenberg, an article including much useful general information about the ecology of caves and underground streams. G. P. W.

The Origin of the Solar System.*

By SIR JAMES JEANS, F.R.S.

THE observational astronomer generally feels only an indirect interest in the problem of how our earth and its companion planets came into being; his telescope can give him no direct information on the subject, since such planets as other suns may possess are too small and too distant to be observed. If every star in the sky were suddenly to give birth to planets we should in all probability remain unaware that anything was happening.

Yet the problem is of thrilling interest to science in its widest sense. The old nebular hypothesis of Laplace had pictured the stars as shrinking nebulæ which rotated faster and faster as they shrank, and in so doing threw off their equators rings of matter, each of which was destined in time to condense into a planet. This cosmogony implied that the shedding of planets was a normal event in the life of a star. It led to the concept, so commonly held in the nineteenth century, that every star in the sky was a sun distributing light and heat to a retinue of worlds circling round it. As solar light and heat are the most obvious essentials for terrestrial life, it was natural to take the next step and assume that every star we saw in our telescopes was busily at work radiating energy to maintain life on its surrounding planets. When once this step had been taken, no great violence to the probabilities seemed to be implied in taking the further step of assuming that each star had been created to this special end.

The more modern view supposes that the birth of planets is very far from being a normal event in the life of a star—it is an abnormal and exceedingly rare event. So rare is it that, even if the stars have already lived the longest lives that have ever been suggested for them—lives reaching back many millions of millions of years into the past—only a minute fraction of them can be surrounded by planets. If they are destined to live into the future for the longest period that has ever been suggested—a period measured in hundreds of millions of millions of years—even by the end of this inconceivable length of time only a minute fraction of their total number will be surrounded by planets. This view implies that most stars must live and die without giving birth to planets at all—and even of those that do, the majority must be so cold and shrunken before their planets are born that there can be little or no question of their sustaining life.

In brief, the older theory, with the help of a little kindly imagination, depicted a universe teeming with life. The more modern theory depicts a universe which proceeds steadfastly on its way, while here and there, in insignificant corners and at infrequent intervals, a strange accident results in life stumbling into being. It can scarcely be a matter of indifference to science—and still less to humanity—which picture is correct.

Let us first consider some evidence of a purely physical nature. The activity of radium appears at first glance to be permanent; yet we know that it is no more permanent than anything else in Nature. All radium gradually loses its potency; it deteriorates, so that after about 1600 years it will be only half as potent as it is to-day.

The reason for this loss of potency is now well understood. It is that the radium gradually changes into something which is not radium, and has not the properties of radium—the debris of radium, let us call it. After 1600 years, a mass of pure radium becomes changed into half radium and half debris of radium. The potency is reduced to half because the amount of radium is reduced to half.

It follows that if we are given a mixture of radium and its debris, we can tell how long the radium has been at work to produce this debris. For example, if the amount of debris is equal to the amount of radium, we know that the disintegration of the radium has been in progress for 1600 years; if three-quarters of the mass is debris the process has been in action for 3200 years, and so on.

The time needed for a mass of a radioactive substance to change into half substance and half debris is known as the 'half-period' of the substance: it varies enormously for different substances. It is 1600 years for ordinary radium; for one radioactive substance, radium C′, it is only about a millionth of a second, while at the other end of the scale are substances for which the half-period is measured in thousands of millions of years. For thorium it is about 16,500 million years; for uranium, 4500 million years.

Now in various rocks in the earth's crust geologists come upon imprisoned uranium accompanied by debris of uranium. In no case is the mass of debris ever as great as the surviving mass of the uranium. There is only one possible inference—the uranium has not been imprisoned for as long as 4500 million years. The proportion of debris found in all samples of rock tells much the same story—the uranium has been imprisoned for a time of the order of 1500 million years. The rocks in which thorium is imprisoned have much the same thing to say—the thorium has been imprisoned for a time of the order of 1500 million years. We conclude that something like 1500 million years must have elapsed since the crust of the earth solidified. We can now add something for the time before solidification and we shall obtain the total age of the earth. From a study of the relative abundance of ordinary uranium and its isotope actino-uranium, Rutherford has been able to show that this total age cannot have been more than about 3400 million years.

---

* Address delivered at the Franklin Institute in Philadelphia on May 20, on the occasion of the presentation of the Franklin Medal to Sir James Jeans.

Shooting-stars or meteors confirm the story told by the earth's rocks. Occasionally one of these objects is too large to be completely vaporised by the resistance of the air, and what is left of it strikes the earth in the form of a large rock or stone known as a meteorite. Many of these bodies are found to contain imprisoned thorium or uranium, along with the debris of their disintegration. The amount of the latter makes it possible to estimate the length of time since the stone solidified. The time cannot be estimated with great accuracy, but no body that has been examined suggested a period of more than 2900 million years since solidification, and the majority appeared to be of about the same age as the earth. In a general way we may say that the length of time which has elapsed since the planets and other members of the solar system solidified cannot have been more than about 3000 million years.

This estimate depends solely on recent advances in physical science. The earlier cosmogonists had no means of forming such an estimate, and it would have been of little use to them if they had. It is important for us of to-day, because we can combine it with recent astronomical knowledge. We can tell how much the sun and stars have changed in 3000 million years. The sun is radiating its substance away at the rate of 360,000 million tons a day. This sounds like a very rapid rate of loss until we compare it with the huge total mass of the sun. We then find that radiation at this rate for 3000 million years scarcely affects the sun's mass at all. The mass of the sun, and indeed of all the stars, must have been very much the same 3000 million years ago as to-day. Furthermore, recent astronomical research has shown that the physical state of a star depends almost entirely on its mass —stars which have approximately the same mass as the sun are found to have also approximately the same physical constitution as the sun. Thus we must suppose that when the planets and meteors were born, the sun not only had the same mass, but also the same physical constitution and size as it has to-day.

This conclusion, based on evidence which can scarcely be challenged, provides a test which we may apply to the various theories of the origin of the solar system in turn. Let us first apply it to the most famous of all, the nebular hypothesis of Laplace. Laplace supposed that the sun started as a huge nebula, extending out as far as the orbit of the farthest known planet—to-day we must say as far as the orbit of Pluto ; as it shrank with cooling it left behind it rings of matter which afterwards condensed and formed the separate planets. When the earth was shed, this nebulous sun would have a diameter equal to the present diameter of the earth's orbit. We see at once that this hypothesis cannot survive the test I have just described ; and indeed there are many other tests, mainly of a dynamical kind, which it is equally unable to survive.

It would be an impossible task to test all the various theories of the earth's origin which might be propounded one by one. Let us notice that all such theories fall into two distinct classes, according as they suppose that the sun alone was concerned in the process of creating the planets, or that other bodies were concerned in addition to the sun.

If the sun alone was concerned it is difficult to discover by what mechanism the outermost planets could be projected to their present distances from the sun. We seem compelled to postulate some system of internal explosions as the origin of the planets, and this seems inconsistent with the present orderly arrangement of the planetary orbits. It also fails to explain why the systems of Jupiter and Saturn are so exactly like the main system of the sun in every respect except size. Indeed, this likeness is so marked that any theory which fails to explain it may safely be dismissed ; we may be sure that the same mechanism must have produced these smaller systems as had already produced the main system. This test seems fatal to any hypothesis of explosions. It is straining probabilities far too much to imagine that a succession of explosions could produce anything so orderly as the main system of planets ; it is straining them infinitely more to suppose that the same miracle could be repeated twice again to produce the similar systems of Jupiter and Saturn.

Thus there seems to be no alternative to supposing that at least one other body besides the sun was concerned in the birth of the planets. In 1750, Buffon imagined the planets to have been splashed out of the sun as the result of collision with a passing comet. In 1880, Bickerton propounded a somewhat similar theory, except that he replaced the comet by a star. This collision theory has recently been revived, with further modifications, by Jeffreys. Although his views call for further discussion and critical examination, it is difficult to see at present how they can possibly be reconciled with the similarity of the systems of Jupiter and Saturn to the main system. Grant for the sake of argument that a big splash formed the planets, then it seems quite beyond the bounds of probability that two smaller, but otherwise almost exactly similar, splashes should occur to create the systems of Jupiter and Saturn.

I believe I was the first, in 1901, to consider the possibility of the second body not colliding with the sun, but producing planets by tidal action. In 1904, Profs. Chamberlin and Moulton independently considered the same possibility, and developed it, along lines of their own, much further than I had done. They imagined that a series of solar eruptions, such as normally cause prominences, were so intensified by the tidal action of a neighbouring star that the ejected matter was projected clear of the sun's gravitational field, where it condensed into small solid bodies, which they designated as ' planetesimals '. These in turn underwent further aggregation and in due course formed the planets.

The scheme which they propounded seemed to me to be open to many objections. Not only did it fail to explain why the satellite systems of Saturn and Jupiter should resemble the main planetary system, but also it failed to explain why satellite systems should exist at all. Indeed, it is doubtful whether it can even explain the existence of the planets. Puffs of gas such as Profs. Chamberlin and Moulton imagined to condense into planetesimals would not condense into solid bodies at all. They could not do so inside the hot atmosphere of the sun, and as soon as they got clear of the sun's atmosphere they would merely scatter into space, like the leak of gas from a gas-burner. Calculation shows that any body of gas will do this unless it is of enormously greater mass than the supposed planetesimals. The mutual gravitational attractions of the molecules of a mass of gas of planetesimal dimensions would be too small by a factor of several millions to result in condensation in opposition to the ordinary gas pressure resulting from the kinetic energy of their motion.

Because the planetesimal theory seemed open to these and other fatal objections, I tried to trace out mathematically the course of events which would actually occur when a second star approached to within a specified distance of the sun and passed on its course without an actual collision taking place. Discarding all physical assumptions as to solar eruptions and the formation of planetesimals, I found that my own old conception of tidal action was able of itself, without any adventitious assumptions, to give a plausible account of the origin of the solar system. In this way I was led to propound a new theory of the origin of the solar system in 1916, which was very different from that of Chamberlin and Moulton.

The researches of Roche (1850) had already shown that every large mass such as the sun is surrounded by what may properly be described as a 'danger-zone'. No body of moderate size can revolve permanently inside this danger zone; it is rapidly broken up into minute pieces. Roche suggested that Saturn's moons and rings provide an example of this; the moons are all outside the danger-zone, but the rings are just inside, whence it is generally believed that the rings are the broken fragments of what was originally an ordinary moon of Saturn. There are good reasons for conjecturing that the system of asteroids which surrounds the sun forms a second illustration of the same effect.

Mathematical investigation of the tidal action between two stars showed that this concept of a danger-zone is equally applicable when two bodies merely approach one another temporarily and then pass on their respective courses. Two bodies which remain always at more than a certain distance from one another merely raise tides like those which the moon raises on the earth. As their distance lessens the height of tide increases; as it increases again the tides fall, until finally both bodies are left in their original undisturbed state But if the two bodies approach to within a certain critical distance of one another, the whole character of these tides changes. Instead of a small elevation travelling over the surface of the disturbed body, as ocean tides travel over the surface of the earth, we have a huge mountain of gaseous matter which continually increases in height as the bodies approach, and finally shoots out to form a long arm which may finally, if conditions are favourable, establish contact with the second body. The two bodies will then be joined by a filament of gas, much as the two ends of a dumb-bell are joined by the handle of the dumb-bell. Under other conditions contact may fail to be established, and a long filament of gas will be left projecting from the primary body in the direction of the secondary body. It can be shown that this filament must inevitably, as the result of the mutual gravitational attractions of its own molecules, condense into detached masses. We can even calculate how massive these condensations will be. No great accuracy is possible, but we find that such condensations would at least be of the same general order of magnitude as the actual planets.

Before condensation commenced, the filament would be shaped like a cigar or a torpedo; one of the two pointed ends is the peak of the tidal mountain, the other is the last thin dribble of matter which came off just as the gravitational pull of the receding star was failing. After condensation we should expect to find the largest condensations near the centre, where the matter was originally richest, with the size of condensations tailing off at either end.

This exactly represents the present arrangement of the planets. It explains why the central planet Jupiter is the largest, and why the sizes and the weights of the planets both show a general tendency to fall off as we recede from Jupiter in either direction. The discovery of Pluto, which is, I suppose, quite certainly less than Neptune both in size and weight, has recently provided welcome confirmation of this prediction of the theory. It is perhaps also significant that, on the whole, the densest planets are not the most massive planets, in which we might reasonably have expected to find the matter most tightly packed, but those which lie nearest to the sun, although these are of comparatively small weight. These came from the root of the tidal mountain, and it seems possible that the heavier elements were more abundant here than at the peak of the mountain. The puzzlingly low density of Saturn, only one-eighth of that of the earth, is at once explained if we suppose that Saturn was formed mainly out of the higher strata of the sun's atmosphere.

We can, however, elaborate the theory in much greater detail than this. The planets at present move in orbits which are almost circular, but this must inevitably result from their having ploughed their way, for thousands of millions of years, through the dust and debris of space. When the planets first condensed they would be describing quite erratic, and indeed almost random, orbits about the sun. Their orbits could scarcely be expected to show any regularity beyond that of all lying in the plane of motion of the passing star which had brought them into being. Those planets which passed near enough to the sun would enter its danger-zone and be broken up in turn, just as the sun had previously been broken up by entering the danger-zone of the other star; the plane of their motion would be that containing the orbit of the planet round the sun. In this way we get a conjectural explanation of the satellite systems of the planets, of their general resemblance to the main system, and of the fact that their orbital planes lie mainly in the plane of the solar system.

In time the planets would cool, then liquefy, and then solidify; the largest would remain gaseous for longest. Now a theoretical investigation of the question shows that planets which remained gaseous until after the birth of their satellites would be likely to give birth to a large number of small satellites, whereas planets which had already liquefied or solidified would be likely to give birth to a smaller number of large satellites—or possibly to no satellites at all. This at once explains a further regularity in the arrangement of the solar system. The planets which have the greatest number of satellites are the two big central planets, Jupiter and Saturn. These have nine satellites each, and all are very small in comparison with the planets round which they revolve. Like the main solar system, the satellite systems of Jupiter and Saturn show the characteristics to be expected in systems born out of a gaseous body. As we proceed away from these giant planets in either direction we come to planets whose satellites are fewer in number, but larger in size relative to the sizes of their primaries—the characteristics to be expected in systems born out of a liquid, or liquefying, body. This is at once explained if we suppose that the great size of Jupiter and Saturn caused them to remain gaseous for a long time, while the smaller planets such as Mercury and Venus liquefied or solidified almost at once. The cases of transition appear to be provided by our own earth in the one direction and by Neptune in the other; each of these planets possesses a single satellite which is abnormally large in comparison with the size of its primary.

We can perhaps find confirmation of this in the fact that Mars and Uranus, the two planets which come next to these as we pass inwards towards Jupiter, are both abnormally small; we might have expected Mars to be intermediate in size between the earth and Jupiter, and Uranus to be intermediate in size between Neptune and Saturn. Now if we suppose that these two planets were the smallest of all the planets which retained their gaseous condition for long, they would suffer more than the others from the continued dissipation of their atmospheric layers into space. On this view Mars and Uranus must be regarded as mere relics of far larger masses, and we see at once why they are abnormally small for their positions in the planetary sequence.

There are so many conjectural elements in this theory that it would be rash to claim, or even to hope, that it can in any way prove final. The highest claim I would make for it is that it accounts for many of the observed facts, and has not yet been found to suffer from insuperable objections—and this can be said of few, if any, other hypotheses as to the origin of the solar system.

If we accept it we must accept also the consequences I stated at the outset. Stars are very rare objects in space, and so are spaced very far apart, so far apart that it is very hard to imagine the sparseness of stars in space. If we take three particles of dust and place them in a large cathedral, this would be incomparably more crowded with dust than space is with stars. As a consequence stars approach one another very rarely, and it is an almost inconceivably rare event for two stars to come so close that planets are born. Planets, and so presumably life also, must be exceedingly rare in the universe.

We can regard this with satisfaction or the reverse, as we choose. Some will feel overwhelmed with a great loneliness; they will feel that it adds to the terror which overcame Pascal when he contemplated the immense voids of space. Others will view it with satisfaction, because it adds to the relative importance of human and terrestrial life. When we thought of each star as the centre of a system which teemed with life, human life appeared as a very small thing; it formed an inconceivably small fraction of the total life of the universe. The new view compels us to think of life on earth as forming a comparatively large fraction of all life of the universe.

George Graham, F.R.S., 1673–1751.

On Nov. 24, 1751, at night, a funeral procession left a shop bearing the sign of the Dial and One Crown, in Fleet Street, for Westminster Abbey. The hearse was preceded by three coaches containing the pall-bearers Dr. Knight, Mr. Watson, Mr. Canton, Mr. Short, Mr. Catlyn, and Mr. Bird, and was followed by nine other coaches. Thus was borne to his last resting-place George Graham, widely known both at home and abroad as the finest mechanician of his day. Arrived at the Abbey, the coffin was carried into the nave and was then laid beside that of Thomas Tompion, who had died in 1713, recognised as "the father of English watchmaking". The grave is not far from that of Newton. It is covered by a stone with an inscription, a part of which refers to Graham, "whose curious inventions do honor to ye British genius whose accurate performances are ye standard of mechanical skill". In the middle of the eighteenth century burials in the Abbey were more frequent than they are to-day, and it was a fortunate decision which led to the interment within its walls of these two famous masters of horology.

Graham, who was a Quaker both by upbringing and by conviction, was cast in much the same mould as that other Quaker and man of science of a later day, John Dalton. Born in Cumberland in 1673, at the age of fifteen he came on foot to London and there began an apprenticeship of seven years with Henry Aske, a clockmaker. His apprenticeship ended, he entered the employ of Tompion, afterwards marrying his niece and succeeding to his business at the Dial and Three Crowns, Fleet Street. In 1720 Graham moved across the street to the Dial and One Crown to a shop which was destined to become famous, and it was there he died, Nov. 20, 1751. The friend of Newton, Halley, Molyneux, Hadley, Bradley, and many others, Graham lived for the advancement of science and the benefit of mankind, and though his business brought him ample means, so little account did he take of wealth that on principle he refused to accept interest on loans and never invested in Government securities. To his more intimate contemporaries he was known as honest George Graham.

Of the life of such a man we cannot know too much, and both horologists and astronomers will read with interest the pamphlet issued by the *Vassar Journal of Undergraduate Studies*, giving Miss C. D. Hellman's sketch of George Graham, maker of horological and astronomical instruments. Miss Hellman has taken the trouble to consult most of the original works which give information of Graham's scientific inventions and observations and her account is the fullest we have hitherto seen. Graham's position among his fellows can be judged from the facts that in 1720, when he took up his residence at the Dial and One Crown, he was elected a fellow of the Royal Society, and that two years later he was made Master of the Clockmakers' Company. He had already invented the 'dead beat' form of the anchor escapement for clocks and watches, and in 1721 had brought out his mercurial pendulum, an improvement which became of great importance.

With these inventions to his credit, Graham then proceeded to add to his reputation by observations on the magnetic needle, during which he discovered the diurnal variation and measured the magnetic intensity. In 1725 he made his well-known 8 ft. quadrant for Greenwich Observatory and at the same time constructed sectors for both Molyneux and Bradley. Much of Bradley's work at Kew was done with his assistance. Other instruments he made were those supplied to the French Academicians who in 1736 visited Lapland to measure an arc of the meridian. At his house in Fleet Street he observed comets, solar and lunar eclipses, sometimes by himself, sometimes with a fellow-observer. He also served on a committee connected with Greenwich Observatory, and carried out work in connexion with the standards of measurements. On all these matters Miss Hellman gives an account, and her pamphlet contains extracts from Graham's paper published in the *Philosophical Transactions*. Without an equal in his own line, Graham lived to see the rise of Mudge, Harrison, Dollond, Bird, Short, and others, in whose hands scientific instrument making reached a pitch of excellence surpassing even that of Graham. Most of these, however, owed something to Graham, and Bradley once wrote: "If my own Endeavours have, in any respect, been effectual to the advancement of astronomy, it has principally been owing to the advice and assistance given me by our worthy member, Mr. George Graham, whose great skill and judgment in mechanics, joined with a complete and practical knowledge of the uses of astronomical instruments, enable him to contrive and execute them in the most perfect manner". "No greater tribute than this", says Miss Hellman, "could be paid to George Graham."

Obituary.

Dr. Richard Wettstein.

The death on Aug. 10, at the age of sixty-eight years, of Dr. Richard Wettstein, Ritter von Westersheim, Hofrat, professor of systematic botany and director of the Botanic Garden and Institute of the University of Vienna, removes a notable figure from the botanical world. His commanding presence, courteous demeanour, and powers of oratory give credence to the statement by the correspondent of the *Times* that on more than one occasion he was seriously considered as a possible president of the Republic.

Among botanists, Wettstein was known as a careful and painstaking investigator, a capable teacher, and an efficient organiser. He studied at Vienna under Anton Kerner von Marilaun, author of the well-known volumes on the natural history of plants, and, after a short period as a *privatdocent*, went in 1892 to Prague, where he followed Heinrich Willkomm as professor of botany in the German University. Seven years later he returned to Vienna to succeed Kerner, whose daughter he had married, as University professor and director of the Gardens. Shortly after his return, a commodious botanical institute was erected to replace the historic but meagre old buildings at the Gardens, and here Wettstein played the part of host to the delegates who met to formulate the Rules of Botanical Nomenclature at the International Botanical Congress in 1905, of which he and Prof. Julius Wiesner were joint presidents. More recently, as senior president of the International Horticultural Congress, in September 1927, Wettstein again welcomed botanists and horticulturists from all parts of the world at the University.

In 1889, while still *privatdocent* at Vienna, Wettstein succeeded Alexander Skofitz as editor of the *Oesterreiche Botanische Zeitung*, which he continued to edit, with some assistance in later years, until his death. The volumes of this journal contain numerous contributions from him relating to the Austrian flora, of which he was a careful student, to systematic botany, and to nomenclature. The journal took a leading part in preparation for the discussions on nomenclature at the Congress in 1905. In 1901, Wettstein led a botanical expedition to South Brazil under the auspices of the Austrian Academy of Sciences, the results of which he published in the *Denkschrift* of the Academy.

Wettstein's chief contributions to botanical knowledge lay in the application of principles of phylogeny and morphology to taxonomy. His monograph of *Euphrasia* (1896) was an intensive study of the species, and their origin and affinities, especially in relation to their geographical distribution. He also developed the idea of *Saisondimorphismus*—the evolution of early and late flowering forms of one stock—as a source of new species. A similar study of a group of European gentians appeared in the following year. He had previously (1891) contributed accounts of the families Solanaceæ and Scrophulariaceæ to the "Pflanzenfamilien", and a "Beitrag zu Flora Albaniens" was published in 1892 as a volume of the "Bibliotheca Botanica". He was a good draughtsman and his botanical contributions are illustrated largely by himself. To botanical students, Wettstein is familiar as the author of a widely used "Handbook of Systematic Botany" (1901–8); he attempted to derive the Angiospermous flowering plant from the Gymnosperms through the Gnetales, regarding *Casuarina* as the most primitive existing Angiosperm. The theory was an ingenious one, but has not been generally accepted.

Wettstein was honoured by his fellow-countrymen and also received many marks of recognition from European and overseas societies and institutions. He was elected foreign member of the Linnean Society of London in May 1914.

A. B. RENDLE.

WE regret to announce the following deaths:

Mr. M. M. Pattison Muir, senior fellow of Gonville and Caius College, and formerly prælector in chemistry in the University of Cambridge, on Sept. 1, aged eighty-two years.

Prof A. S. Pringle-Pattison, emeritus professor of logic and metaphysics in the University of Edinburgh, on Sept. 1.

Dr Droop Richmond, chief analyst to Boots Pure Drug Co., Nottingham, for sixteen years, on Aug. 26, aged sixty-four years.

Dr. Per Axel Rydberg, for the last thirty-two years curator of the New York Botanical Garden in the Bronx, on July 25, aged seventy-one years.

Dr. Louis W. Sambon, a pioneer worker in tropical medicine, on Aug. 31.

Col. the Hon. Milo G. Talbot, C.B., who was awarded a Royal Medal of the Royal Geographical Society in 1909, known for his surveys of the north-west frontier of India and Anglo-Egyptian Sudan, on Sept. 3, aged seventy-six years.

News and Views.

THE very personal appeal of the problems of the internal secretions is sufficient guarantee that the valuable résumé by the master in this subject which appears as a Supplement to this week's issue of NATURE will be widely read. Both author and subject came into being at about the same time and both have grown and developed side by side. During the eighty odd years of a fruitful scientific life, Sir E. Sharpey-Schafer has not only witnessed the change of view regarding the basis of animal behaviour but also he has played a prominent part in bringing about this broader basis. It is being realised more and more that racial and individual characteristics are not solely the expressions of an inherited nervous system but are also dependent, though to a lesser degree, on the development and efficiency of the organs of internal secretion. Many unwarrantable assertions appear from time to time regarding the part played by these special glands in the determination of personality, and until further information concerning their variations with age, climate, and habitat are available, such statements must continue to remain of a highly speculative nature. As in all subjects, during the constructive period, some confusion creeps into the nomenclature, but up to the present no better term has been introduced to connote an internal secretion than the word 'autacoid' proposed by Schafer to express the drug-like action of such a chemical regulator; it is more accurate though less euphonic than the term 'hormone' introduced by Starling, which was originally intended to suggest excitation only and would thus exclude depressing autacoids.

THE methods of studying these autacoid substances are based largely, first of all, on the loss or removal of the particular gland, with observation of the resulting deficiency disease set up, and secondly, with the cure of the disease by grafting or feeding with the gland from a healthy animal, or alternatively by injection of an extract of the gland, and lastly by administration of the active chemical principle when this is known. The method which has been most extensively used and has proved the most fertile in ascertaining important facts is the injection of extracts into animals and into man. This technique was not used much until Schafer, working in conjunction with Oliver, discovered that extracts made from the adrenal bodies give rise—when injected into the veins of an animal—to a very great increase in blood pressure. It is worthy of mention that all the fundamental facts were noted by Schafer in his early papers. In his work with Oliver he observed that one other gland extract besides that of the adrenal, namely, the pituitary, also contained a pressor principle, and an extract of this gland is now widely employed by obstetricians for the arrest of hæmorrhage after childbirth. The account of the interrelationships of the organs of internal secretion given by Schafer does not warrant the present-day wholesale dissemination of poly-glandular preparations coming from foreign drug manufacturers.

Progress in the elucidation of the mode of action and therapeutic action of a specific autacoid can be established only by careful dosage and observation of a physiologically standardised unit.

CONSIDERABLE interest has been aroused recently by the claim of Dr. Bendien, of Zeist, to have developed a method of diagnosis of cancer which is infallible even in the early stages of the disease. The method has been briefly described by Dr. A. A. Miller in a recent letter to the *Lancet* (Aug. 22, 1931; p. 427) and is given in more detail in a paper by F. C. Smith, E. R. Holiday, and J. Marrack (*ibid.*, Aug. 29, p. 507). It consists of two parts: in the first the serum is mixed with a series of mixtures containing varying proportions of sodium vanadate and acetic acid: normal human serum produces a precipitate in tube No. 6: if flocculation occurs below this, that is, in the more acid mixtures, carcinoma, tuberculosis, or some other disease is indicated. In the second part of the test, the precipitate obtained is heated to 56° C., filtered off, weighed, and dissolved in two per cent sodium bicarbonate solution. The ultra-violet absorption curve of this solution is then obtained by means of the spectrophotometer. Bendien claims that there is a curve typical of cancer and another of tuberculosis.

MARRACK and his co-workers (loc. cit.) in their investigation of the test, point out that the concentration of the precipitate in the bicarbonate solution is very variable owing to the fact that it is only dried by suction on the filter, so that it contains water up to 90 per cent of its total weight. No attention can be paid, therefore, to the actual height of the absorption curve obtained; only the shape and slope are significant. They obtained curves of the same general character as those of Bendien, but they found that the actual slope depended on a time factor. When the spectrophotometric examination is carried out as soon as the precipitate has been dissolved, both cancerous and non-cancerous cases show a typical 'tuberculosis' curve with absorption extending into the visible region of the spectrum, as indeed might be expected from the yellow colour of the solutions. On standing, however, the solutions fade slowly, and no longer absorb the longer wave-lengths: curves 'typical of carcinoma' are then obtained. The authors conclude that the method is of no value in the diagnosis of cancer. It is clear that further work is required before Bendien's claim can be accepted without question: it is possible that the different opinions expressed as to the value of the test may be due to differences in technique, but in any case, Marrack's work indicates that to be of value the details of the test must be very rigidly standardised.

INVESTIGATORS have long sought to discover the cause of the common cold. The condition is unquestionably contagious, and has therefore been considered to be a microbial infection. Many micro-organisms have at different times been assigned a causative rôle, and the evidence adduced in favour of one or another agent has frequently seemed to be impressive. Several well-recognised pathogenic micro-organisms, such as the pneumococcus, streptococcus, influenza bacillus, and *Micrococcus catarrhalis*, have been thought to play a part in the production of this catarrhal condition, the severer form of which was formerly often spoken of as an 'influenza cold', but none can be said to have established a position other than as a possible occasional cause. With the recognition of the existence of the ultra-microscopic or filtrable forms of disease-producing viruses, evidence accumulated that the causative agent of the common cold might belong to this class of infecting agents. This hypothesis receives confirmation by the studies of A. R. Dochez, K. C. Mills, and Y. Kneeland, jun. (*Lancet*, Sept. 5, p. 547), who found that the chimpanzee in addition to man is susceptible to an acute infection of the upper respiratory tract, resembling in every respect the similar infection in man.

MESSRS. Dochez, Mills, and Kneeland have filtered nasopharyngeal washings from individuals with acute colds through Seitz filters, which do not permit the passage of bacteria, and the filtrates were inoculated intranasally into chimpanzees, with the result that a typical acute attack of 'cold' developed. Human volunteers similarly inoculated also manifested the signs of the common cold, and such experimental colds both in apes and in man are contagious by contact to others, and may be passed in series from individual to individual. The virus in the filtrates preserved anaerobically in the ice-box maintained its activity for from four to thirteen days. A method of culture was also devised in a chick-embryo cystein broth medium. This was inoculated with the filtered nasal washings and the culture was carried on for twelve generations, when an inoculation with it induced a mild cold in one out of three human volunteers. The fifteenth culture, representing a dilution of approximately one to two quadrillion of the original material, also produced colds in two out of three inoculated volunteers. In addition to initiating symptoms of infection, the virus also appears to provoke increased activity of any potential pathogenic agents that may happen to be present in the respiratory tract, such as the pneumococcus and others.

ON July 7–20, representatives of the Geological Surveys of Southern Equatorial Africa met at Kigoma to discuss the compilation of a geological map of that part of the continent. The conference constituted the first meeting of the Sub-Commission of African Geological Surveys formed at the Fifteenth International Geological Congress, at Pretoria in 1929, and the countries represented at Kigoma were: French Equatorial Africa, Northern Rhodesia, Belgian Congo, Ruanda Urundi, Uganda, Tanganyika Territory, and Nyasaland. In these countries, provisional geological maps already exist, but great difficulty has hitherto been found in establishing the relation between the geological formations of any one country with those of neighbouring or more distant countries, and this difficulty has been greatest in the case of the ancient unfossiliferous formations. In the course of the recent discussions, however, assisted by a comparison of rock specimens and maps from the different countries, considerable progress has been made, and as a result of this the Sub-Commission has drafted a geological map of Southern Equatorial Africa, which it is proposed to publish at an early date. A great advance has been made in the mapping of the Katanga System, within which lie the great copper deposits of Northern Rhodesia and the Belgian Congo, and the tin-bearing formations of Uganda can be followed through Tanganyika and Ruanda Urundi to the Belgian Congo. Moreover, the Karroo System, bearing many coal deposits in this part of Africa, was discussed in some detail.

SINCE the only sound basis for the development of mineral resources is a thorough knowledge of the geological formations and of their relation to one another, the discussions at the conference and the conclusions arrived at, as summarised in the new geological map, should prove to be of considerable economical value, as well as of scientific interest. The conference recognised the following three important systems of pre-Karroo age: (*a*) The Basement Complex, comprising sedimentary and igneous groups showing wide variations in degree of metamorphism; this system is roughly comparable with the Swaziland System of South Africa. (*b*) The Muva-Ankole System, consisting principally of quartzite and shales, with acid volcanic rocks locally, and, more rarely, basic rocks. In some areas the shales are represented by phyllites or schists, and the quartzites show a similar range of metamorphism. The system can be traced from Northern Rhodesia to Uganda, and includes, for example, the Muva, Mafingi, Ukinga, and Karagwe-Ankolean groups. It is separated from the systems below and above by vast uncomformities, and it is considered as probably equivalent in part to the Witwatersrand and the Ventersdorp Systems. (*c*) The Katanga System, ranging from the Série des Mines to the Upper Kundelungu, and equivalent to the Transvaal-Nama and Waterberg Systems. At the base of the Lower Kundelungu is the great tillite of the Katanga, so that in this area at least one important glacial epoch of pre-Karroo age is recognised. It may be added that over a wide area in this part of Africa glacial deposits are believed to exist at the base of the Karroo, although their correlation with the Dwyka has not yet been established.

THE special displays of the flood-lighting of buildings in London which began on Sept. 1 and are being given in connexion with the International Illumination Congress have proved a great success and have attracted huge crowds of sightseers. The flood-lighting has brought out the beauty of many architectural features of the buildings which are seldom noticed. For example, the upper façade of Somerset House fronting the river is bathed in a clear rose-coloured light which makes a striking contrast with the dark terrace beneath. Buckingham Palace is perhaps the most brilliantly illuminated building, and makes a very attractive spectacle. The lamps required for it consume 200 electric units per hour. The principal area illuminated is from the Tower Bridge to Westminster. The clock tower of Parliament is flooded with light the colour of old ivory, and can be seen from great distances. The spire of St. Bride's Church, shown up in brilliant white light, also frequently catches the eye when driving through the City. The Institution of Electrical Engineers, on the Embankment, with its six bright pylons, is admired by many. We understand that this illumination is permanent. The illuminations include monuments and parks. From Northumberland Avenue the silhouette of Nelson on his column is a wonderful sight. The column itself is in darkness, and the statue, gently illuminated, stands out in detailed relief. Some well-known buildings in the neighbourhood of London have also been flood-lighted. The George Inn at Slough and the Dysart Arms at Petersham show up the merits of this system of lighting. In a few cases the display is a little garish, but the brighter the spectacle, the better pleased are the sightseers.

THE limitations produced by atmospherics on long-distance working between radio stations are very annoying to radio operators. The commercial operation of a long-wave receiving station may remain completely disorganised for long periods when intense atmospheric disturbances take place near the aerial. A flash of lightning acts as a long-wave spark transmitter, and as the voltage is in millions and the current in thousands of amperes, the effects produced may be very serious. Lightning flashes are not the only cause of atmospherics. The distribution of potential throughout the atmosphere is very irregular and it is probable that sudden equalisations of potential may occur without visual flash, causing all kinds of atmospherics. In *Television* for August, T. Bray points out that television is much less affected by atmospherics than radio communication. It might usefully be employed, therefore, in sending printed messages during heavy tropical atmospherics when ordinary radio cannot be used. Atmospherics manifest themselves as a rapid series of 'splashes' on the television screen, affecting it continuously and sometimes resembling flames passing over it. Bray shows by diagrams that even when aural and automatic reception of the morse code are impossible, the printed letters on the television screen are easily read. This special aspect of television may open out new commercial applications where it can be usefully employed.

NEWS from the *Nautilus*, the submarine in which Sir Hubert Wilkins is making his Arctic expedition, was received by radio by the *News Chronicle* from 350 miles from the north pole, where the ship was on Aug. 25. The actual position was then about lat. 84° N., long 10° E. Echo soundings had shown an irregular ocean floor varying between 1000 fathoms and 300 fathoms within a few miles. This was probably at the place where the *Nautilus* crossed a submarine ridge between northern Spitsbergen and Greenland. Farther east, at a position not stated, a depth of 1205 fathoms was recorded. At the time of the message the ship was in open water with much scattered pack-ice, but closer pack, involving the need to submerge, was expected to the northward. Progress was slow, and spray was freezing on the deck and conning tower. A message sent the previous day recorded a serious accident. The *Nautilus* was then 500 miles from the pole, when it was discovered that the diving rudder was lost. A diver discovered, however, that the ordinary steering gear was intact. The loss of the diving rudder made submergence difficult and restricted movements below the surface, but later in the week a message recorded progress. During last week no messages were received from the *Nautilus*, and a certain amount of anxiety was felt. The Norwegian Government decided to send a search expedition and two aeroplanes, under the command of Capt. Riiser-Larsen. A long dispatch from Sir Hubert Wilkins appears in the *News Chronicle* of Sept. 7, from which it appears that the *Nautilus* has been holed and emerged from the pack ice on Sept. 4 in about lat. 81° N., long. 11° E.; she was making her way slowly to Spitsbergen. It is stated that the scientific staff of the expedition are well satisfied with the results obtained.

A MEETING was recently held of the Sub-Committee on Symbols, Units, and Nomenclature used in Physics, appointed by the International Union of Physics. Sir Richard Glazebrook was appointed chairman of the Committee. Prof. Kennelly, as chairman of the Section of the Advisory Committee of the International Electro-Technical Commission dealing with electrical and magnetic magnitudes and units, wrote directing attention to the meeting of his Committee in London on Sept. 18, and inviting members of the Committee of the International Union of Physics to attend. This invitation has been accepted, and it has been arranged to hold a meeting of the Sub-Committee on Symbols, Units, and Nomenclature shortly afterwards to continue the discussion commenced at Brussels. Communications with regard to this meeting should be addressed to Dr. Ezer Griffiths, at the National Physical Laboratory, Teddington.

THE claim by Sir Colin Mackenzie, of Canberra, that the female aboriginal skull discovered in the Jervois Ranges is one of the most important of the prehistoric documents in the world to-day has been received with some scepticism in Australia. The skull is 173 mm. in length, the forehead breadth is 86 mm., and the volume between 956 c.c. and 980 c.c. It is contended that this cubic capacity is the smallest known in any complete human skull; hence that the skull belonged to an individual on the confines of the lowest humanoid stock. On the other hand, Prof. F. Wood Jones, of the University of Melbourne, is convinced, from the study of a cast, that the skull falls well within the limits of the normal modern Australian aboriginal female, and that Sir Colin Mackenzie's conclusions are unwarranted.

THE *Spectator* for Aug. 15 contains an article (p. 210) by D. Yorke on bird migrants at Rossitten, in which are some noteworthy observations on the relation of peregrines to their prey. The first one seen made five attempts to capture wood-pigeons from the migrating flocks, but always failed, even when it got into a flock and flew amongst them; ultimately it caught a greater spotted woodpecker and descended to eat it. Later, three peregrines were in sight at once, also attacking pigeons unsuccessfully; and again a woodpecker of the above species fell a victim. This would seem to indicate that the wood-pigeon, though greatly desired, is too much for many peregrines, and that the greater spotted woodpecker occupies to them the same relation as a warningly-coloured moth or butterfly does to insect-hunters—a sort of emergency quarry to be taken in default of anything better. It was proved a generation ago that the Danaid butterflies will be eaten by caged insectivorous birds in default of other live food, and the coloration of most woodpeckers would be classed as 'warning' if worn by an insect.

WE have received a letter from Mr. F. Gilbert Carruthers, 10 Addison Road, London, W.4, relative to the question whether earwigs use their forceps for purposes of offence or defence. He mentions that he inadvertently drank some soda water from a mug which contained one of these insects, and that the first intimation he received of the creature's presence was when he experienced a distinct nip on the lip. The nip, he adds, was more surprising than painful. In this connexion it may be mentioned that, when alarmed or disturbed, earwigs regularly open their forceps in a threatening manner. If a finger, or other object, be placed between the forceps, the latter will often close with a slight nip. The main function of these weapons is still obscure: on rare occasions earwigs have been recorded to use their callipers for seizing their prey, and also for fighting against one another.

SIR WILLIAM R. MORRIS has given £25,000 to the British Empire Cancer Campaign for the establishment of a research fellowship in radiology at the Mount Vernon Hospital, Northwood, Middlesex. This hospital was opened in 1929 as the Empire centre for the treatment of patients suffering from cancer, and for the investigation of the causes and cures.

THE twelve major topics announced for discussion at the third International Conference on Bituminous Coal to be held under the auspices of the Carnegie Institute of Technology, Pittsburgh, on Nov. 16–21 (see NATURE, Feb. 14), are as follows: cleaning and preparation; hydrogenation; by-products; fertilisers; low and high temperature carbonisation; gasification; combustion; railway and steamship fuel; smoke abatement, dust removal, and flue gas purification; origin, classification, and properties; competition between coal and other fuels; storage of coal. The following countries are among those to be represented: United States, Austria, Great Britain, Czechoslovakia, France, Germany, the Netherlands, Poland, U.S.S.R., Spain, and Switzerland.

J. A. A. KETELAAR has asked us to correct an error made by him in his letter in NATURE of Aug. 22, p. 303, entitled "Structure of the Trifluorides of Aluminium, Iron, Cobalt, Rhodium, and Palladium". The value of the z-parameter of the fluorine ions (2) is not $\frac{1}{8}$ but $\frac{5}{8}$, in accordance with the description of the structure at the end of the letter.

Supplement to NATURE

No. 3228 SEPTEMBER 12, 1931

The Physiology of Internal Secretion.

By Sir E. Sharpey-Schafer, F.R.S.*

PHYSIOLOGY must be looked upon as having begun with Harvey. As a science, therefore, it dates back merely three hundred years. It is only during the last one hundred and fifty that it has made real progress, and much of that progress has taken place during the last hundred.

During the period immediately succeeding Harvey's discovery of the circulation of the blood, the attention of physiologists was mainly devoted to the mechanical functions of the body. After Harvey, Stephen Hales was the first to study the mechanics of the circulation. Hales determined the amount of pressure which the blood exerts in the arteries; like a true student of Nature, he did not restrict himself to studying the flow of blood in animals but also investigated the conditions of the flow of sap in plants. In the meantime, it had been found by Malpighi, using the newly invented microscope, that the blood is not homogeneous but a suspension of coloured corpuscles in an otherwise colourless fluid. Nothing, however, was as yet known as to the real nature of blood or as to its functions. Nor was it until the foundations of chemistry had been established by Lavoisier that light was thrown upon the supreme importance of those functions. It has been reserved for the time in which we live to determine the constancy of composition of the circulating fluid and the necessity to health and even to life itself of maintaining that constancy within a very circumscribed limit.

The recognition of the regulation of bodily functions by the nervous system constituted the next step in advance in physiology. This recognition occurred about a hundred years ago. Since then it has been justly regarded as the dominating factor in the physiology of the Metazoa. The definite founding of this doctrine was due to Carl Ludwig in Germany and Claude Bernard in France. Side by side with these researches, others by various workers (Magendie, Bell, Flourens) were revealing the manner in which the central nervous system co-ordinates the functions of the various organs of the body. In our own times, the doctrine of the dominance of the nervous system and the manner in which all reflex and voluntary actions are regulated by it has been firmly established by the researches of Pavlov and Sherrington.

Thus the predominant feature of the development of physiology up to this time has been the evolution of knowledge of the regulation of bodily functions through the nervous system.

A 'new physiology', which does not supersede the old but assimilates and is incorporated with it, has sprung up within the last fifty years. The old physiology was based, as we have seen, on *nervous regulation*; the new physiology is based on *chemical regulation*. We have learned to recognise that the functions of organs are not governed solely by nerves but are largely influenced by chemical substances in the blood; the nerves and nerve-centres being themselves subject to chemical influences. On the other hand, chemical regulation may itself be influenced by the nervous system, so that the reaction is mutual.

Since the chemical substances which react with the tissues are normally produced elsewhere than in the tissues they act upon—many of them in special organs of internal secretion—their action is often spoken of as *humoral*, because they are conveyed in the blood or lymph (humours). But this term is too restrictive, for they may be actually produced in situ within the tissues upon which they act: in such a case, their action, although still chemical, would be incorrectly described as humoral.

Regulation by chemical substances appears to be a more simple process than regulation through nerves: it might therefore be supposed that chemical regulation would have been the first to be evolved. But this can scarcely be the case, for chemical regulation assumes the existence of a circulating fluid to convey the chemical materials for such regulation to the tissues on which they act, whereas nervous regulation is already developed in the lowest of the Metazoa, such as the medusæ, before the evolution of any circulatory system. The nervous system of these low forms of animal organisation, although much less complex, is already constituted of discontinuous units in no respect essentially different from the neurones of the higher animals, and serves to regulate their activities without, so far as we can tell, the aid of chemical or humoral stimuli.

---

* From the John Mallet Purser Lecture delivered in Trinity College, Dublin, on June 26.

ORIGIN OF THE DOCTRINE OF INTERNAL SECRETION.

The history of the development of our knowledge regarding chemical as distinguished from nervous regulation, or, in other words, of the doctrine of internal secretion, is of considerable interest. The first indication that the regulation of function might be effected by chemical rather than nervous agencies was pointed out by Berthold in 1849. Berthold found that the implantation of testicular grafts into castrated cocks (capons) would restore the appearance of the birds to that of normal cocks, and concluded that the testicles must pass some substance into the blood which reacts on the organism in general. He was thus the first to introduce the idea of 'internal secretion'. But for many years his observation remained unnoticed. The idea was almost grasped by Claude Bernard, who in 1852, as the result of his work on glycogenesis, described the passage of sugar from the liver cells into the blood as an 'internal secretion', and recognised that every tissue in the body must be continually passing products of metabolism into the blood, either for nutrition or excretion, and must therefore be yielding similar 'internal secretions'. But this was a long way from the modern interpretation of the term, which implies material of a special nature capable of exerting a specific action. One cannot, therefore, claim Bernard as a founder of the new physiology.

The next distinct move in the establishment of the doctrine of internal secretion came from the clinicians. The Swiss surgeons, J. L. and A. Reverdin and Th. Kocher, described, in 1883, as the result of extirpation of the thyroid gland, a peculiar cachexia which was termed by Kocher 'cachexia strumipriva' and by the Reverdins 'operative myxœdema'. They compared it with the conditions which accompany atrophy of the gland in children or its degeneration in the adult. These conditions had already been described by Gull in 1874 and later by Ord in 1878, and the resulting affection had been termed 'myxœdema' from the peculiar œdematous condition which characterises the skin, which was supposed to be due to the presence of mucin.

That myxœdema is due to the absence of an internal secretion of the thyroid is shown by the fact that, if not too advanced, all the symptoms are removed by administration hypodermically (or even orally) of thyroid juice or extract of thyroid. The chief ingredient of the secretion is thyroxine, the chemical constitution of which has been exactly ascertained, thus enabling it to be produced synthetically. Thyroxine can be substituted for thyroid juice or gland extract and will remove the consequence of removal or atrophy of the gland.

Apart from the isolated observation of Berthold, the thyroid was thus the first of the endocrine organs to furnish definite evidence not only of the existence but also of the importance of an internal secretion. In the absence of its secretion, nutrition and growth are impaired and the functions of the brain, especially those of the cerebral cortex, can no longer be carried on normally; while administration of the gland substance or of its chief ingredient will restore the cretin to a normal condition both bodily and mentally. As Gley has remarked, we are faced with the remarkable fact that the highest functions of the brain cannot be carried out in the absence from the blood of a relatively simple chemical substance. And this substance is formed by a gland which is not connected either anatomically or developmentally with the central nervous system but is related primitively to the alimentary canal. Moreover, the internally secreting function of the thyroid is, so far as our present knowledge goes, independent of the nervous system. It can be carried on if the thyroid is entirely cut off from connexion with that system as by severance of all nerves passing to the gland or by transplanting it from the neck to some other position in the body.

The internal secretion of the thyroid was, as we have seen, discovered about fifty years ago from the results of surgical removal of the organ in man. These results were confirmed and amplified by experiments on animals, and form the actual beginning of our knowledge of the internal secretions, the existence of which had not previously been recognised. All the various internally secreting organs, now recognised as fulfilling functions of the highest importance, were until then regarded as mere rudimentary structures devoid of function : which may at some early period of evolution have had a meaning but had long ceased to exercise any influence in the animal economy.

In 1855, Thomas Addison described the disease which bears his name, and associated the symptoms of the affection with destruction of the suprarenal capsules. ' Addison's disease ' is characterised by extreme debility and is invariably fatal. The publication of Addison's memoir led to the performance of experiments by Brown-Séquard and others with the view of determining whether surgical extirpation of the capsules would produce effects in animals similar to those accompanying their destruction by disease in man. Although the pigmentation effects seen in Addison's disease were never observed in animals, these experiments showed that complete removal of both capsules was invariably fatal. Attempts made by implantation of capsules from other individuals to antagonise the effects of removal always proved abortive, and the cause of the fatal result of extirpation could not at the time be ascertained. Nearly forty years more elapsed before the suprarenal capsules were recognised as organs of internal secretion, owing to the discovery that a powerful, physiologically active material is produced in the medulla of the organ.

The discovery was made in 1893. On testing the effects of intravenous injection of extracts of a number of organs, including the chief ductless glands, it was found by Oliver and Schafer that while extracts of most organs produce a distinct fall of blood pressure, extracts of suprarenal and of pituitary cause an immediate and extraordinary rise. While this active substance of the pituitary has never been isolated in a pure state, so that its chemical constitution remains unknown, that of the suprarenal is obtainable in a crystalline form. It can also be prepared synthetically, and constitutes the now well-known drug ' adrenaline '. Adrenaline was the first of the active principles of the internal secretions to be isolated and synthesised and for long remained the only one, but it has now been joined by thyroxine.

Adrenaline and thyroxine may be taken as yielding examples of two entirely different kinds of action of the internal secretions. Adrenaline produces its effects immediately—upon heart, blood vessels, liver, salivary glands, intestine, pupil, spleen—but the effects soon pass off, owing to destruction of the adrenaline either in the tissues or within the vessels. Thyroxine, on the other hand, acts slowly and gradually, influencing the nutrition of the tissues, stimulating the multiplication of cells, and producing characteristic effects upon general metabolism. These results do not appear immediately and do not readily subside, but are continued long after the administration of the thyroxine has ceased ; they may even be cumulative, so that a dose which seems insufficient at first may, if continued, produce an exaggerated effect.

Adrenaline and thyroxine also furnish examples of a striking difference between the mode of secretion which occurs in different endocrine organs. Thus, adrenaline is passed from the cells of the suprarenal medulla, in which it is formed, directly into the blood ; whereas the internal secretion of the thyroid does not pass directly into the blood, but passes from the vesicles, in which it is secreted by their lining cells, into the lymph in the interstitial spaces of the connective tissue of the gland, and from these into efferent lymphatics, and eventually into the blood by the great lymphatic trunks.

On consideration of all the organs and parts of organs which are credited with the production of an internal secretion, it will be found that those which contain sinusoids, into the blood of which the secretion is passed directly by the cells of the organ, are—besides the suprarenal medulla—the liver, the islets of Langerhans of the pancreas, the pars anterior of the pituitary body (perhaps also the pars tuberalis), the parathyroids, and the placenta ; whilst the internally secreting organs which resemble the thyroid in possessing ordinary capillaries and pass their secretion into the lymph of the organ are the cortex of the suprarenal capsules, the pars intermedia and pars nervosa of the pituitary, and the gonads. Naturally, it does not follow that the efferent lymphatics are the only vessels which absorb the material of the internal secretion from the interstitial lymph of such organs ; it may also be absorbed in part from the lymph by the blood capillaries. The distinction is that in one case it is passed directly into the blood and produces its effects immediately, whereas in the other case its passage into the blood is slower and its effects are produced more gradually.

There can be no doubt that a real physiological distinction underlies this difference of the mode of secretion: and we may probably draw the inference that in the case of secretion directly into the blood, it is momentarily varying—increasing or diminishing—according to the immediate calls of the organism ; and that when reaching the blood through the lymph, its purpose is to cause such gradual changes as those affecting growth and nutrition.

Relations of Internal Secretions to Nervous System.

The internal secretion of some endocrine organs is independent of the nervous system, their activity or inactivity being directly influenced by constituents of the blood. Thus an increase of blood sugar will provoke an increased secretion of insulin from the islets of Langerhans. With other endocrine organs the case is different; their internal secretion is dependent on the nervous system. Of these, the medulla of the suprarenals furnishes an example. It can be shown that the adrenaline it forms is dependent for its secretion into the blood upon the integrity of the nerves passing to the organ. If the splanchnic is cut, the secretion of the corresponding suprarenal capsule is arrested; if now the peripheral end of the cut nerve is stimulated, the secretion is poured into the blood. Normally this influence is exerted through a nerve centre in the bulb, in the same way that the secretion of the salivary glands is poured out as the result of afferent stimuli affecting the reflex centre for salivation. This salivary centre can be influenced not only to increase but also to diminish or arrest the secretion, and, *ceteris paribus*, this is also true for the secretion of the suprarenal medulla, which can be influenced to secrete more or less adrenaline according to the nature of the stimulus reaching the bulb. This influence is the falling or rising of arterial pressure. Anything which tends to lower blood pressure produces an increase of the secretion, anything which tends to raise blood pressure produces a decrease of the secretion: and as a larger amount of adrenaline in the blood has the effect of raising arterial pressure and a diminished amount tends automatically to lower it, an average arterial pressure is thus maintained by a system of self-regulation exercised reflexly.

The chief afferent nerves for the reflex are those distributed to the carotid sinus—the bulbous extremity of the common carotid artery where it bifurcates into the internal and external carotids. This part of the vessel is richly supplied with nerves, as is also the small carotid gland which lies at the bifurcation. The researches of H. E. Hering and of J. F. and C. Heymans have demonstrated conclusively the fact that most of the vascular reflexes which are brought about by variations in arterial pressure are effected through the nerves of the carotid sinus and carotid gland. Whenever the sinus becomes more distended by an increase of arterial pressure, the vasomotor centre becomes inhibited and dilatation of the arteries of the body generally is produced. Similar effects produced through the agency of the depressor nerve have been longer recognised, the effect of its stimulation in lowering blood pressure by causing dilation of arteries through the vasomotor centre having been discovered by Cyon (working under Ludwig) so long ago as 1866.

As Tournade has shown, however, the raising and lowering of the blood pressure in the aorta and carotid sinus affects not only the vasomotor centre in the bulb but also an adrenaline-secreting centre, and this, by causing a variation in the amount of adrenaline poured into the blood, assists the regulating action of the vasomotor centre.

Detection of Adrenaline in Blood.

When first the presence of so powerful a stimulant of the vascular musculature was shown to be yielded by the suprarenal medulla, it was conjectured that the physiological purpose of the secretion must be to aid the nervous system in maintaining the tone of the arteries and in keeping up their blood pressure. But attempts to demonstrate that there is a normal or physiological secretion of adrenaline into the blood were made in vain by many experimenters. It was admitted that such a secretion could be produced by stimulation of the splanchnic nerves and by stimulation of the bulb either directly or through drugs; and also that an increase of secretion would be evoked by violent emotions and would show itself by producing the usual effects of adrenaline—the 'emotional secretion' of Cannon. But as it proved impossible, using even the most delicate physiological tests, to determine that adrenaline is present in the blood under resting conditions, the idea that it is being constantly secreted as a normal physiological act was given up. The question has, however, been answered in the affirmative by Tournade (working for the most part in collaboration with Chabrol) by the use of a new method of experimentation.

Two animals—generally dogs—are used for each experiment. Both are fully anæsthetised with chloralose. From one (*A*), both suprarenals are removed; from the other (*B*), preferably the larger, only one, usually the right. The whole of the blood coming from the remaining (or left) suprarenal of *B* is allowed to pass into *A* by making connexion between the suprarenal-lumbar vein of *B* and the external jugular vein of *A*. *A* therefore receives all the adrenaline secreted by *B*. *A* may be termed the 'receiver', *B* being the 'donor'.

The blood pressure of each animal is recorded from the femoral artery by mercury manometers. If anything is done to *B* which affects its secretion of adrenaline, the increase or diminution will show itself in the blood pressure of *A* ; *B*, of course, will remain unaffected, the whole of its suprarenal blood being passed into *A*. Hence, if the secretion of adrenaline by *B* is increased, the blood pressure in *A* will rise : if diminished, it will fall. Further, it is known that the intravenous injection of extract of suprarenal medulla, that is of adrenaline, produces in dogs not only a rise of blood pressure due to arterial constriction, but also what is known as a 'vagal pulse'—that is a slow and irregular action of the heart, caused by stimulation of the vagus centre in the bulb by the drug. This irregularity may therefore also be expected to occur in *A* if it is receiving an increased amount of adrenaline from *B*. Other tests of increased or diminished amount of adrenaline passing into *A* may be applied in addition, some of which are more delicate than the blood pressure test.

The following results have been obtained by Tournade by the above method :

1. If the venous connexion between the two dogs is interrupted by pinching, no change occurs in *B*, but in *A* the blood pressure falls, the intestinal movements increase in amplitude, the kidney and the spleen expand. On releasing the vessel, adrenaline effects are immediately again apparent, the blood pressure rises, a vagal pulse becomes apparent, the intestine is inhibited, the kidney and spleen shrink, and so on.

2. If the left splanchnic of *B*—in which, of course, the nerve supply of the remaining suprarenal is contained—is cut, the blood pressure falls in both dogs : in *B*, owing to paralysis of vasomotor nerves to the abdominal viscera; in *A*, in consequence of the failure of the suprarenal of *B* to secrete adrenaline. On now stimulating the peripheral cut end of the splanchnic of *B*, the blood pressure in that animal immediately rises, owing to contraction of its abdominal vessels ; and after a short delay, due to the time taken by the secreted adrenaline of *B* to pass through the venous anastomosis and to reach the circulation of *A*, the blood pressure rises also in this animal and displays the vagal character of the pulse ; besides which, all the other effects of addition of adrenaline to the circulating blood can be observed.

3. If the vasomotor centre in the bulb of *B* is directly stimulated by faradic shocks, there is an immediate rise in the blood pressure of *B* caused by general vascular contraction, and a delayed rise in the blood pressure of *A* due to increase of adrenaline : this is caused by stimulation of the adrenaline-secreting centre in the bulb of *B*. On the other hand, if the fourth ventricle of *B* is painted with dilute solution of cocaine, the activity of the adrenaline centre becomes depressed and less adrenaline is secreted by *B* and passed into *A*, the blood pressure of *A* falls, and the other effects of diminution of adrenaline in the blood of *A* can be observed.

4. If the blood pressure in *B* is lowered by any means, *B*'s adrenaline centre becomes reflexly stimulated, more adrenaline is passed into *A*, and all the effects of the increase become apparent in *A*. On the other hand, any agency which raises the blood pressure in *B*, such as stimulation of a sensory nerve, intravenous injection of a blood pressure-raising drug, re-injection of blood which has been withdrawn, is followed by a diminution of secretion of adrenaline by *B*, and all the effects which such diminution produces are observable in *A*.

5. Even comparatively slight changes in the blood pressure of *B* will cause quite appreciable differences in the amount of adrenaline secreted, so that such fluctuations in blood pressure as are shown by the Traube-Hering waves, or even by respiratory fluctuations when pronounced, are reproduced in *A* in the reverse sense ; every fall of blood pressure in *B* being followed by a rise in blood pressure in *A*, and vice versa.

The experiments of Tournade prove conclusively that this internal secretion is intimately dependent upon the nervous system.

EXCITATION AND INHIBITION.

Returning to the history of the new physiology, the next most striking fact regarding internal secretion, after the discoveries relating to the thyroid and suprarenal medulla, was the observation of Bayliss and Starling (1902) that an extract of duodenal mucous membrane contains a substance which when injected into the blood stimulates the secretion of pancreatic juice. To this substance they gave the name 'secretin', and supposed it to be formed when the acid chyme from the stomach comes into contact with the lining membrane of the duodenum. They spoke of it as a 'chemical messenger' absorbed by the blood from the intestine and carried to the pancreas in order to stimulate that gland to secretion ; and, somewhat later, assuming that all such chemical messengers possess a stimulating function, Starling suggested for them the general term ' hormone ' (stimulant).

Starling included in the term ' hormone ' such products of metabolism as carbonic acid and urea which pass into the blood from the tissues and act as chemical messengers stimulating the respiratory centre and the kidney respectively. More recent writers, in disregard of the original meaning of the term and the definition of it given by its author, have extended it to apply not only to substances which excite to activity but also to substances which have an exactly opposite effect—which, in fact, instead of exciting activity, depress it. We should, however, recognise in our nomenclature that the internally secreting organs yield materials which produce specific effects of two opposite kinds, namely, excitation and inhibition. These two kinds of effect are comparable with those obtained from stimulation of nerves, which we are in the habit of speaking of as ' excitatory ' and ' inhibitory ' and recognising as antagonistic. Antagonistic effects are also caused by drugs—some stimulating to activity, others restraining activity. Now, the active substances of the internal secretions act like drugs and several are used in medicine. Such are adrenaline, thyroxine, parathormone, insulin, as well as the active substances of liver and stomach, of the pituitary body, of the ovaries, placenta, and testes. As with nerves and as with drugs, some of these active substances are excitatory, others are inhibitory. They assist the excitatory and inhibitory nerves to maintain that constancy of physical and chemical condition which seems to be essential to life. They act as ' balancers ', throwing their weight first on one side, then on the other, so as to preserve a normal equilibrium.

The resemblance between the action of the internal secretions and that of drugs is very close : the active substances they contain are, in fact, drugs. This close resemblance should be incorporated in the nomenclature ; it is unfortunate that this was not originally done. Starling, who was a pioneer in their investigation and was particular to point out their drug-like character, was not aware that they may be either excitatory or inhibitory : he supposed that their action is always to produce excitation. It was for this reason that he invented the term ' hormone ', having selected that name because it expresses ' excitation ' (ὁρμάω, I excite). The example which led to the adoption of the name was ' secretin ', which excites the pancreas to secrete pancreatic juice ; as we have seen, Starling compared this action with that of carbon dioxide, which excites the respiratory centre to activity. He accordingly proposed the name ' hormone ' for all substances, whether organic or inorganic, carried by the blood for the purpose of exciting the cells of any organ to activity. At the time that he wrote (1906) our knowledge of the constituents of the internal secretions was comparatively limited, and it was supposed that they must all act like secretin and possess an excitatory action. The term ' hormone ' seemed, therefore, suitable.

Presently, however, when the knowledge of the action of internal secretions became extended, it was apparent that they not only stimulate to increased activity but that they also serve the antagonistic rôle of diminishing or restraining action. To express the latter the term ' hormone ' is inappropriate, since it involves an express contradiction in terms. I accordingly suggested in 1913 that such inhibitory substances might be distinguished as ' chalones ' (χαλάω, I restrain), as expressing both correctly and conveniently the opposite of ' hormones ' ; the term is gradually coming into use, although many authors, especially in the United States and Germany, still confuse chalones with hormones and use the latter term for both. Hormones have been longer known and are supposed to occur more frequently, but it is not improbable that as our knowledge extends it will be found that chalones are just as numerous, and not unlikely that for every hormone there is an antagonistic chalone : the ' law of balance ' of the living organism almost demands this. To denote all such specific principles of the internal secretions, whether excitatory (hormones) or inhibitory (chalones), I suggested the term ' autacoid ' (Greek αὐτός, self, ἄκος, a drug).

In nearly every instance an autacoid is either exclusively hormonic or exclusively chalonic. Adrenaline, which is hormonic in its action on the circulatory system but chalonic in its action on the muscular coat of the alimentary canal, appears to furnish an exception. Occasionally, however, it excites intestinal muscle instead of inhibiting it. All its excitatory activities are paralysed by ergotoxine, its effects being then purely chalonic.

Regulation of Gland-function by Nerves and by Autacoids.

It was already known that the pancreas can be excited to secrete through the nervous system. There is therefore in the case of this gland a dual control, namely, through the nervous system and through an internal secretion. In regard to some externally secreting glands—for example, the salivary glands—we only know of one kind of control, that exercised through nerves. On the other hand, some externally secreting glands are not controlled by nerves at all, but only by substances circulating in the blood; the control being in such cases purely chemical (humoral). This applies to the mammary gland and to the kidney, the secretions of neither of which are directly influenced by nerves, but are freely provoked by substances circulating in the blood. Externally secreting glands may therefore be classed under three heads, namely: (1) those that are exclusively under the influence of nerves, such as the salivary glands; (2) those that are entirely under the influence of chemical substances in the blood, such as the mammary glands and kidneys; (3) those that are influenced both by chemical substances and by nerves, such as the pancreas and gastric glands. The same distinctions appear also to obtain with the endocrine glands; although (except in the case of the suprarenal capsules) less is known about their regulation by nerves.

The doctrine of the regulation of bodily functions by chemical agents may be regarded as having been definitely established with the discovery of secretin. Since then facts have been accumulating at an ever-increasing rate in support of this doctrine, so that a complete change has come about in our conceptions of the working of the body.

Many organs are known to possess the double function of producing materials which are discharged externally and of secreting autacoids internally. The gonads were the first organs to be recognised as having this double function, since besides producing the gametes they also yield an internal secretion to the blood which affects the formation of the secondary sex characters. The discovery of secretin furnished another example. To this was added the pancreas, which not only produces pancreatic juice but also by its islet tissue furnishes insulin. To these still more recently has been added the liver, which besides secreting bile and assisting in metabolism, produces an autacoid which stimulates the hæmapoietic organs. A similar duality of function is furnished by the stomach and kidneys.

In the case of the gonads, their complete removal (castration) has been employed from time immemorial, both in animals and man, and the effects are well known. These effects were formerly thought to be produced through the nervous system, and assumed to be due to the lack of afferent stimuli from the organs in question to the nerve centres. But when it was made clear by implantation experiments and by the administration of extracts that many of the effects of castration can be removed, it was evident that the nervous system is not responsible for the phenomena but that they must result from the action of an agent produced by the gland and carried by the blood to the organ affected. This was indeed the explanation to which Berthold was forced in 1849. The explanation does not exclude the nervous system from influencing the results, but they are obtained without its co-operation.

INFLUENCE OF ENDOCRINE ORGANS ON ONE ANOTHER.

Not the least interesting feature of the study of the internal secretions is the influence exerted by one set of internally secreting organs upon others; the influence is frequently mutual. This is illustrated by the mutual influence of the thyroid and pituitary. Removal of the thyroid causes enlargement of the pituitary, with increase of its secretion. Destruction of the pituitary in the young animal arrests the development of the thyroid. Its secretion stimulates the thyroid. The thyroid in its turn stimulates the suprarenal medulla. The increase of adrenaline thereby caused provokes the liver cells to discharge their glycogen into the blood as glucose, and the hyperglycæmia stimulates the islet tissue of the pancreas to an increased secretion of insulin. This in its turn stimulates and facilitates carbohydrate metabolism and thus affects the activities of many tissues and organs of the body. In this way we can trace a chain of phenomena starting from excitation of the pituitary and linking together organs topographically distant and to all appearance functionally distinct.

Another striking illustration of mutual reaction is the influence of the pituitary upon the sex organs. The size and secretion of the pituitary is affected by the condition of the gonads: removal of the gonads is followed by an increase in size of the pituitary, while destruction of the pituitary is followed by diminution in size of the gonads and ultimately by loss of sexual functions.

It is the pars anterior of the pituitary which is concerned with the sex organs. For it can be shown that the cyclic changes in the ovary and uterus which characterise the period of sexual activity are initiated and conditioned by autacoid substances produced in the pars anterior, so that in the absence of these substances (as after removal of the pituitary) maturation of the ovum and its fixation in the uterus is no longer possible. Its activity can, however, be restored or, in immature female animals, can be aroused by implantation of anterior pituitary or by hypodermic injection of its extracts. To influence the ovary the anterior pituitary produces two distinct hormones. One stimulates the ovaries, even in immature animals, and produces maturation of the Graafian follicles. The enlarging Graafian follicles produce in their turn an internal secretion containing an autacoid (folliculin) which causes ovulation and starts changes in the uterus, preparing it for the reception of the discharged ovum if fertilised. A second hormone of the anterior pituitary causes the corpora lutea which are formed from the discharged follicles to produce another autacoid (lutin) which promotes further alterations in the uterus, preparing it for the fixation of the ovum. The corpora lutea also yield a chalone which prevents the further action of folliculin and the further discharge of ova.

All these autacoids of the pituitary and ovary can be detected in the blood. They are found in it in greater amount during pregnancy than at other times, and pass out from the blood into the urine, so that if a few drops of the urine of a pregnant woman are injected under the skin of an immature mouse, the growth of the ovaries of the latter is stimulated, the Graafian follicles enlarge and discharge their ova, corpora lutea are precociously formed, and changes characteristic of œstrus occur in the uterus and vagina. The effects thus produced on the ovaries of immature mice constitute the Zondek-Aschheim test for pregnancy now in general use. It furnishes a striking example of the application of the new physiology to clinical medicine, others being the curative effect of thyroxine in myxœdema, that of insulin in diabetes, and that of liver or stomach extract in pernicious anæmia.

FUNCTIONS OF THE PITUITARY.

The pituitary gland consists of several parts, and each of those parts yields its own specific autacoids. That the anterior lobe is concerned with growth is evidenced by the fact that it is greatly enlarged in acromegaly and gigantism—affections characterised by hypertrophy of the body in general and of the skeleton in particular—while its administration to growing animals both increases their rate of growth and causes them to become of more than ordinary size. On the other hand, if the anterior lobe is atrophied or by any means diminished in size, growth is slowed and dwarfism results; while its removal in growing animals is followed by arrest of growth. There is also reason to believe that it produces a chalone which acts antagonistically to the growth hormone. Metabolism in general and the metabolism of carbohydrates in particular is influenced by it: one result being the production of obesity, which is observed in cases of disturbance of its endocrine function, and interference with the action of the autacoids which regulate the metabolism of fat. Also, as we have seen, it exerts an enormous influence upon the gonads.

The other parts of the pituitary are also connected with many and varied functions. The pars intermedia and pars nervosa are closely interlocked and difficult to separate. The pars intermedia is formed of epithelial cells; the pars nervosa is developed from brain substance and consists mainly of neuroglia cells and ependyma fibres. In the spaces between these fibres are peculiar colloidal masses which are formed from the cells of the pars intermedia and can be traced through the pars nervosa to be discharged into the cerebrospinal fluid of the third ventricle. They are known from their discoverer as 'Herring's bodies'. If extracts are made of the pars nervosa and injected into the blood vessels, powerful effects are obtained upon the arteries, the heart, the intestinal muscle, the muscular tissue of the uterus—all of which are stimulated—and the mammary glands, which, if lactating, are caused to secrete. The kidneys are also stimulated so that the amount of urine is increased; but if the extracts are administered hypodermically instead of intravenously, the effect is antidiuretic. Such extracts act therefore in two directions upon the secretion of urine, either stimulating or inhibiting; they therefore contain two antagonistic autacoids affecting its secretion, a hormone and a chalone.

The action of extracts of posterior lobe on the uterus is powerful and specific; contraction of the organ is caused by an infinitesimal amount of the so-called 'oxytocic' hormone. Since the secretion of this lobe is discharged into the cerebro-spinal fluid, this fluid also acquires the properties of the extracts. The uterine action is most marked during gestation and the action is strongest near parturition, which it assists and perhaps initiates. An extract of the posterior lobe of the pituitary constitutes one of the most useful medicaments of the accoucheur.

Another action of extracts of the posterior lobe, probably due to a chalone produced in the pars intermedia, is that of causing expansion of the melanophores of Amphibia so that the animals become dark: this is a specific effect, no other natural substance being known to produce the same result. On the other hand, removal of this part of the pituitary body in Amphibia results in contraction of the cutaneous melanophores, so that the animals become pale and offer a great contrast to the effect of injection.

Thus the pituitary body influences by its internal secretions a large number of diverse functions. It is extremely probable that each function is influenced by a different autacoid ; some by two antagonistic autacoids : this is the case with the diuretic and antidiuretic effects. Nevertheless, up to the present, it has proved impossible to isolate any one of the active substances. By the employment of different solvents extracts have been obtained which contain more of one autacoid than of others, but no one autacoid has been got in a pure condition.

AUTACOIDS OF THE GONADS.

Although the pituitary body is the endocrine organ the secretion of which influences more numerous functions of the body and produces more diverse effect than any other, several have multiple effects. This is the case, for example, with the gonads, for besides the internal secretions of the Graafian follicles and corpora lutea which have already been considered, these organs produce other autacoids on which the secondary sex characters depend. The autacoids to which these characters are due are not formed by the reproductive cells themselves but by special cells in the connective tissue between them, known in the testis as ' interstitial cells '. That the secondary sex characters are not dependent on the true reproductive elements is evidenced by the fact that these characters are developed after destruction of the true reproductive elements. Extracts of gonads in which the reproductive cells have been eliminated contain all the substances which promote the appearance of secondary sex characters ; their administration will cause the production of these characters even in castrated animals. Thus a castrated animal, which, whatever was its original sex, may be regarded as neuter, can be made to assume the secondary characters of either the male or female sex by administration of extract of testicle or ovary as the case may be, or by implantation of portions of one of those glands. Extracts of the gonads also contain antagonistic substances which prevent the appearance of the secondary characters of the opposite sex.

TISSUE AUTACOIDS.

There is another class of autacoids, not produced in internally secreting organs and not passing into the blood, but produced in situ in the tissue they are to influence. We may term them ' local ' or ' tissue autacoids ', as distinguished from those we have hitherto considered and which may be termed in contradistinction ' blood ' or ' circulating autacoids '. The ' tissue autacoids ' have only been discovered recently, and we have very little accurate information regarding either their nature or their mode of activity. Such knowledge as we possess has been mostly derived from experiments upon the heart.

Whilst investigating the possible chemical changes produced by stimulation of the vagus nerve upon the frog's heart, Loewi (1921) found that Ringer's solution which had been used for perfusing a heart inhibited by the vagus, would, if introduced by perfusion into another frog's heart, itself produce an inhibitory effect upon the second heart. Evidently the impulses descending by the vagus have caused the formation of an autacoid which, by chemical action, reproduces the effect of the nerve itself. An electrocardiogram obtained during its action resembles that obtained during stimulation of the vagus. The autacoid produced by the vagus may possibly be the actual cause of the inhibitory effect of that nerve rather than its consequence. This substance is termed the ' vagal substance ' or the ' vago-mimetic autacoid ' : obviously it is an inhibitory substance or chalone. It can also be obtained from the mammalian heart (Rijlant). Atropine, which prevents the production of inhibition of the heart through the vagus, does not prevent the formation of the ' vagal substance ' : it does, however, prevent this substance from slowing or inhibiting another heart on which it is allowed to act. The vagal substance resembles acetyl choline in many respects and may be identical with this.

Similarly it is found that after stimulation of the sympathetic fibres to the heart an autacoid is produced which stimulates a second heart to increased rate and force—in fact, reproduces the action of the sympathetic : this may be termed the ' sympathetic substance ' or ' sympatho-mimetic autacoid '. Its action is nullified by ergotoxine, as is the action of the sympathetic. It is obviously a chemical substance produced under the influence of the sympathetic and seems to be identical with adrenaline. Being a stimulating autacoid, it is, of course, a hormone and is antagonistic to the vagal chalone. It is possible that it is owing to the local production of these autacoids in the part of the heart which is supplied by the vagus and sympathetic nerves that the inhibitory action of the one and the accelerator and augmentor action of the other is actually due.

The formation of these vagal and sympathetic substances is probably the explanation of the continuance of vagal and sympathetic action which is always observed for an appreciable time after stimulation of the respective nerves has been discontinued—a phenomenon which has hitherto received no adequate explanation. Their formation may also account for the relatively long latency period between stimulation and commencement of response, with which all who have observed the effects on the heart of nerve-stimulation are familiar, and for which a reasonable explanation has hitherto been lacking.

These observations upon the autacoids produced in the heart as the effect of stimulation of its antagonistic nerves are comparatively recent, but they serve to recall an observation made by Demoor in 1913. Demoor found in the dog that extracts of a submaxillary gland which had been caused to secrete actively for some time by stimulation of its branch from the chorda tympani would, if injected into another dog, also produce in the second animal active secretion from its submaxillary gland. He inferred therefrom that an active chemical substance is produced locally in the gland of the first animal, which has the same action on its cells as the chorda tympani and may be the actual cause of the secretion. This again may furnish an explanation of the fact that the secretion takes an appreciable time to start after the stimulation of the nerve is commenced, and a still longer time to cease after the stimulation of the nerve is discontinued; also of the observation that after stimulation of the chorda tympani, stimulation of the sympathetic supply is usually followed by considerably greater secretion than in other circumstances, this being due perhaps to the fact that there is still a remainder of active substance in the gland cells. The active substance in the case of the salivary glands may be saliva itself. Guimaris (1930) found that if saliva from any source, or an alcohol-extract of saliva, is injected into the artery supplying the submaxillary gland of the dog, free secretion is provoked, and that this will happen even if the chorda tympani has been cut and its fibres allowed to degenerate.

Cannon (1930) has brought forward evidence that a substance resembling adrenaline in its action is formed in plain muscular tissue as the result of stimulation of its sympathetic supply. He terms the substance 'sympathin', but suggests that it may be identical with adrenaline. Finkleman had previously found that stimulation of the sympathetic fibres to the intestine results in the production of a substance which when brought in contact with a second preparation of intestinal muscle will cause its inhibition: this obviously suggests the formation of adrenaline. Finally, Ch. Richet *fils* has found that extracts of kidney produce diuresis if injected into the blood.

Observations of this kind suggest that an autacoidal action of gland extracts may be of more general occurrence than has been thought, and that functional changes in cells may be correlated with the formation of autacoids specific for each kind of cell. Probably in the near future there will be discovered many more illustrations of this form of chemical control of the bodily functions. Various experiments indicate the influence upon these functions of such products of metabolic activity as acetyl choline and histamine—both of which have been found by Dale and Dudley in notable amount in various tissues and organs.

Such 'metabolic autacoids' or 'metabolites' may have a local action affecting either the tissues themselves or their blood vessels, causing the vessels to contract or dilate according to the nature of the autacoid set free (T. Lewis). Whether the metabolites are formed as the result of stimulation of nerves or by direct irritation of the tissue is difficult to decide. In any case, the facts indicate that chemical substances are formed, under the influence of nerves or as the result of direct excitation, which act directly on the tissue in which they are produced.

INHERENT AUTACOIDS.

There is yet another class of autacoids which are not produced as the result of excitation by nerves or otherwise, but appear spontaneously or are inherent in the tissue and impart to it active properties. They are chiefly known in the heart, where they have been investigated by Demoor, Rijlant, Zwaardemaker, Haberlandt, and others.

Although it has been known from time immemorial that the heart will continue to beat after removal from the body and therefore possesses in itself a natural tendency to automatic rhythm, it was long thought that this was actually due to nerves and ganglia within its substance. But the researches of Gaskell (1883) on the hearts of fishes, amphibians, and reptiles—confirmed by Engelmann and by many subsequent workers—showed conclusively that the nervous system of the heart has nothing to do with its automatism, which is inherent in cardiac muscle and is most pronounced near the entrance of the great veins and least near the exit of the great arteries. Therefore in a simple heart such as that of a fish the contractions start at the sinus venosus and traverse successively the auricle, the ventricle, and the bulbus aortæ. Gaskell observed that, if such a heart is cut across transversely into segments, the segments will beat spontaneously, but not all at the same rate: the rhythm of the sinus will be the fastest, that of the auricle next; that of the ventricle will be slower than that of the auricle, and that of the aortic bulb the slowest. In the intact heart the rate is always that of the sinus. which is accordingly termed the 'pace-maker'. Gaskell further showed that the dominance of the sinus is due to the fact that its tissue possesses greater excitability than the rest; for if the excitability of any other part is increased locally above that of the sinus—as by the application of warmth—the contractions will now start from the part which has been thus rendered more excitable. In the embryonic heart of the bird and mammal much the same conditions are found as in lower vertebrates, but as development proceeds the distinction of the several parts becomes confused, the venous sinus being merged into the right auricle and the aortic bulb into the ventricle. The only sequence to be clearly seen with the unassisted eye is that described by Harvey, namely: auricular systole, ventricular systole, pause.

It is, however, still possible to show by electrographic methods (T. Lewis) that the contractions actually start from a point in the auricle close to the entrance into it of the superior and inferior venæ cavæ. At this point the thin contractile tissue of the right auricle is marked by a slight swelling—the 'node of Keith and Flack' or the 'sinus node': here the muscular fibres are somewhat peculiar in structure and arrangement, and receive many nerve fibres derived from the vagus and sympathetic. In the same auricle—the right—there is another node of similar structure placed near the base and close to the entrance of the coronary sinus. This is the 'node of Tawara'. From the node of Tawara a circumscribed bundle of muscular fibres—the 'bundle of His'—passes through the connective tissue of the auriculo-ventricular system to the ventricles; the bundle divides into two branches, one for the right, the other for the left ventricle. Each branch ends in a network of peculiarly constructed muscular fibres, the 'network of Purkinje', which covers the interior of each ventricle underneath the endocardium and is connected everywhere with the adjacent fibres of the myocardium. The muscular tissue of the nodes, as well as that of the auriculo-ventricular bundle and that of the network of Purkinje, is different from ordinary cardiac muscle, from which it also differs somewhat in function: it is termed the 'nodal tissue' to distinguish it from the ordinary cardiac muscle.

The contractions of the heart start at the sinus node: from that point they spread rapidly over both auricles, which have their muscular tissue in complete continuity. Reaching the node of Tawara, the contractions then traverse the auriculo-ventricular bundle, and are conducted by it and its branches to the network of Purkinje; from this they spread in the muscular wall of both ventricles. The sinus node is the pace-maker in the heart of the mammal. If it is excised, the contractions assume a slower rate, and the electrocardiogram is altered in type; the rate now being that of the part of the auricle near the entrance of the coronary sinus—'coronary' rhythm. If the bundle of His is severed, the auricles continue to contract spontaneously with the 'sinus node' rhythm. The ventricles, which now have no muscular connexion with the auricles, also continue contracting spontaneously, but with a much slower rhythm. The spontaneous contractions, whether of auricles or ventricles, are dependent on the presence of nodal tissue. Separated portions of right auricle or of either ventricle, both of which contain that tissue, will continue to beat spontaneously and rhythmically: but if the left auricle, which contains no nodal tissue, is completely severed from the right, it soon ceases to beat spontaneously, although it will respond to artificial stimulation; it can also be made to resume its spontaneous contractions by addition of an extract of nodal tissue from the heart of another animal.

The inference is that an excitatory autacoid or hormone is produced in the nodal tissue which is necessary to start the spontaneous contractions, and that this hormone is formed in greatest amount in the node of Keith and Flack. This causes the rhythm of the cardiac tissue to start from that node, whence it is propagated over the whole heart in the manner above described. Demoor found that not only is the left auricle caused to contract rhythmically by adding extract of nodal tissue to the Ringer's solution bathing it, but that it and cardiac tissue generally are also rendered by such addition more sensitive to sympathetic stimulation—this effect being due to a second hormone in the extract, different from that which causes the spontaneous contractions.

As already stated, excision of the sinus node causes the right auricle to assume a slower rhythm. If it is now re-implanted in the situation from which it was removed, the original rate of contraction of the heart is restored (Rijlant), although the continuity of the fibres of the node with the rest of the heart remains, of course, severed. The explanation of this experiment favoured by Demoor is that the tissue of the node continues to produce the active substance or hormone, and that this now diffuses from it and causes increased excitability in the cardiac tissue immediately surrounding it; and thus as long as it survives the graft continues to officiate as the pace-maker. The explanation favoured by Rijlant is that the re-implanted node sets up an electric change with each contraction, and this starts the contractions of the adjacent cardiac muscle at the same rate as those of the node. Should the graft not take, it will before long cease to contract and will presently die. In that event, the heart resumes the rhythm of the coronary part of the auricle. During the activity of such a graft the electrocardiogram is normal; after degeneration it takes on the 'coronary' type.

INACTIVATION OF AUTACOIDS.

The existence in the blood of most of the autacoids of the body, although long doubted, must now be conceded. It is by their variability in amount in that fluid that their effects are shown. This variability implies that there must be some means of eliminating them; otherwise the continuance of their secretion would lead to an accumulation which would before long produce toxic effects even if the normal rate of secretion were small. If the secretion is rapid, then elimination must be equally rapid. That this is the case is illustrated by adrenaline. Unless this were rapidly eliminated or de-activated, the balancing action upon the blood pressure which Tournade has shown to occur would not be possible. We know very little in most cases as to how the elimination or de-activation is produced. In some it may be that the autacoid forms a stable chemical compound with a product of the cell on which it acts and thus becomes inactivated. This is probably the case with adrenaline, which is de-activated by aldehydes (Cramer), and aldehydes constantly occur amongst the intermediate products of tissue metabolism. Some autacoids are not de-activated, but are eliminated by the urine. This is the case with those secreted by the anterior pituitary, the ovary, and the placenta. Or, finally, the action of an autacoid may be arrested by the secretion of another one which is antagonistic to it: the reaction being assumed to be of a chemical nature.

The large number of autacoids which have now been recognised manifests their importance in physiology. A generation or two ago none of these substances was even dreamed of. Our knowledge of them is wholly the result of the observations and experiments of the last fifty years. The changes in physiology which have resulted from this knowledge constitute not merely an advance in degree but also an alteration in character. The doctrine of internal secretion forms a new departure. We must in future explain physiological changes in terms of chemical regulation as well as of nervous regulation. It is therefore justifiable to speak of the doctrine as the 'New Physiology', seeing that it has completely altered our outlook on many of the problems with which physiology deals and consequently on those met with in medicine and surgery.

Quantum-Mechanical Models of a Nucleus.

IN their recent paper,[1] Lord Rutherford and Dr Ellis have shown how the numerous γ-rays of radium C′ can be arranged in a simple and orderly manner, which suggests, as they point out, that the multiplicity of the γ-rays is largely due to the excitation of several α-particles into the same excited level rather than to the excitation of one α-particle into several excited levels. Their arrangement of the lines of radium C′ is probably not a unique scheme of this sort, but any reasonable scheme appears likely (they show) to present the same general features.

It seems desirable therefore to investigate theoretically in detail any simple model or models of a nucleus consisting of some fifty α-particles, which might show such general features. The main feature brought out by Rutherford and Ellis is that the γ-rays can be expressed in the form

$$h\nu = pE_0 - qE_1,$$

where p is an integer running from 1 to 4 and q an integer running from 0 up to perhaps 10; the value of E_1 is about $\frac{1}{16}E_0$ for radium C′ and has much the same value for radium B. For radium C′ more than one value of E_0 may be required.

There are two models which might be investigated with some chance of success; the first is a model in which each α-particle is considered to move independently in a central field (which is ultimately to be referred to the combined interactions with the other α-particles), but the whole family is affected by perturbing interactions of the form $V(r_{ij})$, between each pair i, j of all the α-particles, where r_{ij} is the distance between the α-particles i and j. Such a model is very like an atom of electrons, except that wave functions have to be symmetrical in the α-particles instead of antisymmetrical in the electrons, and this is the essential difference which allows of the states of reduplicated excitation, which do not occur at all in atoms. This model can be still further simplified from a three-dimensional to a one-dimensional form for a first discussion.

The second model is one in which each pair i, j of α-particles act on one another with a potential energy $\frac{1}{2}\lambda r_{ij}^2$. This model is obviously a rather poor physical approximation to the type of force, but it has the advantage that it can be studied exactly and not merely by the approximations of a perturbation method. A discussion of both these models has been begun, but has as yet only been carried through for the first model simplified to one dimension.

Confining attention only to the most general features, likely to be true of any suitable similar model, the following results have been obtained, which are to a large extent in excellent accord with the scheme of Rutherford and Ellis, but also seem to indicate clearly that a rather more elaborate scheme should be adopted. The energy levels of the model which arise from excitation of more than one α-particle into a single excited state are of such a configuration that the corresponding γ-rays (if they could all be emitted) would be approximately of the frequencies

$$h\nu = p(E_0 - qE_1).$$

These frequencies agree with those of the proposed scheme of Rutherford and Ellis if the scheme is only very slightly modified, so that in place of the proposed single set of γ-rays of frequencies $2E_0 - qE_1$, we have the double set of frequencies $2(E_0 - qE_1)$ and $2(E_0' - qE_1)$ with E_0 and E_0' nearly equal, and in place of the single set $3E_0 - qE_1$, the triple set $3(E_0 - qE_1)$, $3(E_0' - qE_1)$, $3(E_0'' - qE_1)$ and so on. It is, moreover, clear that the reduplication of the upper levels is to be expected when we consider the three-dimensional version of the model. Further, the theory suggests that the ratio E_0/E_1 should be numerically somewhat less than $\frac{1}{2}n(=26)$ in not too bad conformity with the observed value 16 for radium C′. The theory even suggests further that both E_0 and E_1, or perhaps rather E_1, will not vary very much between one radioactive nucleus and another. It is true that the observed values of E_1 (but not those of E_0) are much the same for radium C′ and radium B. The γ-rays of other atoms have not yet been analysed in this way.

All these features are general and the conformity very reassuring. One can, however, further estimate the relative frequency of the emission of the various γ-rays corresponding to the transitions from a state of q-excited α-particles to states of $q-1, q-2, q-3\ldots$ excited α-particles. With an interaction energy of the proposed form, the transitions $q \longrightarrow q-3$ should be absent, or at most very rare, and the transitions $q \longrightarrow q-4$, $q \longrightarrow q-5$, etc., entirely absent. The theory gives as a first approximation to R, the ratio of the frequency of occurrence of the transitions $q \longrightarrow q-2$ and $q \longrightarrow q-1$, the value

$$R\left(\frac{q \longrightarrow q-2}{q \longrightarrow q-1}\right) = \frac{q-1}{6 \cdot 5}f,$$

where f is a factor certainly less than unity and probably not so small as $\frac{1}{10}$. The absolute value of the ratio R may be heavily affected by higher order terms, and we need not be concerned if the proposed scheme does not conform closely. The feature of R that is almost certainly of general importance is that R increases with q. This feature ought to be carefully borne in mind in the construction of any amended scheme. It is not yet possible to say whether these features can be incorporated in an otherwise satisfactory scheme, and a detailed re-examination must be undertaken.

The proposed scheme for radium C′ is arranged to include values of p up to 4 and therefore transitions of the type $q \longrightarrow q-4$. These certainly do not, and the transitions $q \longrightarrow q-3$ probably do not, fit into the allowed transitions of the proposed model with the simple interactions proposed. But such transitions can be present if there are terms in the interactions depending essentially on the co-ordinates of three or more particles, not reducible to sums of terms depending on the co-ordinates of only two. Such terms are to be expected in such a close configuration, though one would scarcely expect their effect to be so large. If the proposed scheme proves ultimately to be correct, one may hope to work back from the γ-ray intensities to some knowledge of the magnitude of these triple and higher interactions.

To sum up, one may say that the scheme proposed by Rutherford and Ellis, so far as it has yet been closely analysed, *that is for frequencies only*, seems likely with trivial modifications to conform completely to the requirements of a simple quantum mechanical model so far as these requirements can yet be foreseen. Such a model, however, will make fairly stringent demands on intensity ratios, and as yet no scheme has been proposed and tested with these in mind. One may hope that further work on these lines will prove fruitful.

While these models may well be able to explain the complicated spectrum of radium C′, it is well to remember that the corresponding spectrum of thorium C′ is very much simpler and contains no families of γ-rays—except perhaps very faint ones—corresponding to those of radium C′, which have been interpreted in the scheme as transitions $q \longrightarrow q-2$, $q \longrightarrow q-3$, and $q \longrightarrow q-4$. It has of course, in addition, a very strong isolated γ-ray of very high frequency. If therefore in attempting to proceed with this analysis, which in any event I believe to be important, one is forced finally to conclude that such models will *not* explain the facts for radium C′, there is no call for surprise or disappointment. It may still be that the proposed scheme of $q \longrightarrow q-1$ transitions will account properly for the important *common* features of the γ-ray spectra of radium B, radium C′, thorium C′, and probably other nuclei. It is more than likely that the striking *differences* between the spectra of radium C′ and thorium C′ should be associated with the two extra free protons in radium C′, the atomic weight of which is of the form $4n+2$, while that of thorium C′ is $4n$.

In the models suggested above, the effect of the protons has been ignored primarily because there seems at present no simple way of incorporating them. But it is clear that the general effect of free protons present in normal and excited states will be to cause the set of low frequency transitions $q \longrightarrow q-1$ to be repeated again at higher frequencies but with the same dependence on q, the constant shift between the two sets representing an excitation energy for a proton. Polarisation of a Beam of Electrons by Scattering.

IN view of the recent experimental work of Dymond[1] on the polarisation of electrons by double scattering, it is of interest to make calculations of the effect to be expected, without assuming, as in the author's previous paper,[2] that the number $2\pi Z\epsilon^2/hv$ is small compared to unity, a condition which is not satisfied in practice.

One finds, as before, that the asymmetry in the scattering is very small, unless :

(1) The velocity of the electrons is comparable with c. (2) Both angles of scattering are comparable with 90°. (3) The atomic number of the scattering nucleus is comparable with 137.

With both angles of scattering equal to 90°, and gold for the scattering element, the calculated percentage asymmetry (200 δ of the author's paper) is in the direction found by Dymond, and of the following magnitude, for various velocities, v, of the electrons:

v/c	0·2	0·3	0·4	0·5	0·6	0·7	0·8	0·9	1·0
Energy in kv.	10·5	25	45	79	127	204	340	662	∞
200 δ . . .	0·5	0·2	3·0	11·5	15·5	14	10	5	0

The asymmetry at 70 kv. is thus about five times as much as that found by Dymond. It is difficult to explain why this should be so. Multiple scattering would reduce the polarisation observed, but there should not be much multiple scattering with the foils used. It is improbable also that the Dirac theory of the electron should give a wrong result when applied to the scattering by a Coulomb field, since the results for the energy levels of an electron in the same field are known to be correct. The Spermatogenesis of Ticks.

THE spermatozoa of ticks are provided with a peculiar 'plasmal-rod' or spermatophore which has long been a puzzle to cytologists, but the careful work of Nordenskiöld (1920) on *Ixodes ricinus* Linn. threw considerable light on the subject.

Certain recent observations I have made on the red tick (*Rhipicephalus evertsi*) indicate that the spermatogenesis in this species differs considerably from that given in Nordenskiöld's account, and it exhibits certain peculiar features which are of general theoretical interest.

In sections of an impregnated non-engorged female there was found in the seminal receptacle a tangle of long, thick cords, the spermatophore-cords (Fig. 1, g).

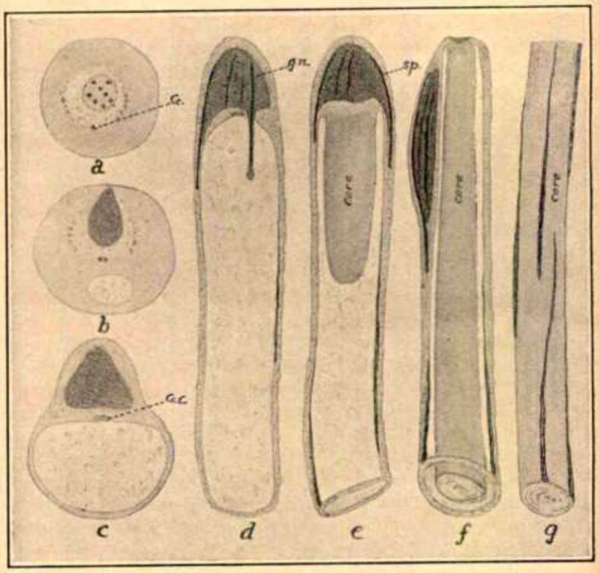

Fig. 1

These are singularly brittle and appear to snap like spun-glass under the microtome-knife, although, doubtless, they are sufficiently flexible in the fresh condition. Each cord carries on its surface a large number of longitudinally arranged filiform spermatozoa, all of which seem to point in one direction. Probably when the eggs are ripe a special secretion is poured into the receptacle, which releases the spermatozoa from the cords.

In sections of a series of male ticks of various ages it was found that each cord and its spermatozoa are formed through the activity of a *single* spermatid. The spermatids, which appear to arise in a typical manner, are unusually large, and it was at once obvious that they are too few to account for the numerous spermatozoa on the spermatophore-cords.

The nucleus of the spermatid bears about eight very small rounded chromosomes. A centrosome (Ce) and possibly mitochondria are present (Fig. 1, a). Nordenskiöld's "centrosomal corpuscle" (CeC) can also be seen ; but the structure apparently vanishes and takes no part in the subsequent development. The spermatid expands and a vacuole with semi-fluid contents arises. At the same time the nucleus enlarges, and it assumes a very finely granular or homogeneous structure with diffuse chromatin which stains only weakly with Delafield hæmatoxylin but intensely with iron-hæmatoxylin (b, c). One or more strongly basophil chromatin-cords are now formed in the nucleus and they pass to its surface. The spermatid becomes tubular, with the nucleus at the top, and as the tube gradually elongates the chromatin-threads are drawn out of the nucleus and lie on the inner surface of the wall of the tube (*d, e*). The chromatin-threads (*sp.*) give rise to the filiform spermatozoa, and the generating nucleus (*gn*) continues to produce them *pari passu* as the tube elongates. The nucleus may remain at the top, or it may slip to one side (*f*), but ultimately it becomes used up and disappears.

During this process a core of homogeneous, compact plasma grows down into the lumen from the top of the tube, immediately under the generating nucleus. The core elongates rapidly and forms a cylindrical rod which is surrounded rather loosely by the original protoplasmic tube carrying the spermatozoa (*e, f*). Afterwards the spermatozoa leave the sheath and become attached to the surface of the core. The sheath disappears, and the core (*g*) with its attached spermatozoa remains as the spermatophore-cord which is transferred from the male to the female.

There is no evidence whatever that fragments of the 'centrosomal corpuscle' become associated with each developing spermatozoon.

It may be added that the nature of the spermatogenesis varies to some extent in different species of ticks of the same genus, since some preliminary observations on the brown tick (*Rhipicephalus appendiculatis*) would appear to indicate that in this species a spermatid produces a cluster of very thin spermatophore-cords in place of one relatively stout one.

The theoretical interest of this remarkable behaviour of the spermatid lies in the fact that in the red tick, just as in certain spiders, a single spermatid gives rise to more than one spermatozoon.

In this connexion it must be specially stressed that there is not the least indication of any approach to a mathematically correct division of chromatin-substance in the production of the chromatin-threads in the generating nucleus, and the size of the resulting spermatozoa is extremely variable, in that the largest may be some three times longer than the smallest. In fact, the chromatin of the nucleus behaves as if it is entirely homogeneous in quality, and any sufficiently large portion of it is capable of producing a spermatozoon.

The upholders of the chromosome hypothesis of heredity will have to explain how it is conceivable, in such cases, for an intricate system of material 'genes' to be passed on from one generation to another.

It is hoped that a detailed account of the observations will be published shortly.

ERNEST WARREN.

Diamagnetism of Liquid Mixtures.

MISS TREW et Dr. Spencer[1] ont mesuré les susceptibilités magnétiques des mélanges liquides suivants : benzène-dichlorure d'éthylène, tétrachlorure de carbone-acétate d'éthyle, benzène-acétate d'éthyle, benzène-tétrachlorure de carbone, eau-pyridine, acétone-chloroforme, acétone-bromoforme, diéthyléther-chloroforme, acétone-trichloréthylène, diéthyléther-acétone. Ils ont conclu de leurs résultats que, en général, la susceptibilité magnétique des mélanges de deux liquides organiques ne suit pas la simple règle des mélanges. Cependant les mélanges de benzène et de dichlorure d'éthylène obéissent à cette règle.

Si l'on porte en abscisse la composition moléculaire du mélange et en ordonnée la susceptibilité magnétique ou la densité de ces derniers mélanges, on obtient une droite. Ce sont des mélanges idéaux. Pour les mélanges de tétrachlorure de carbone et d'acétate d'éthyle, on trouve aussi sensiblement une droite pour la densité et la susceptibilité magnétique. Pour tous les autres mélanges on obtient des courbes qui présentent un maximum dans le cas de benzène-acétate d'éthyle, pyridine-eau, acétone-chloroforme, diéthyléther-chloroforme, diéthyléther-acétone.

Selon les mêmes physiciens la mesure des susceptibilités magnétiques permet d'affirmer si des changements physiques ou chimiques se forment en mélangeant des liquides organiques et cette méthode est très sensible.

Ranganadham[2] a fait remarquer que ses mesures personnelles ne confirment pas celles de Miss Trew et Dr. Spencer. Ainsi, pour les mélanges de benzène et tétrachlorure de carbone, Ranganadham obtient une droite parfaite pour exprimer la relation entre la susceptibilité magnétique et la composition. Pour les mélanges acétone-chloroforme il trouve, entre les valeurs mesurées et celles qui sont calculées par la règle des mélanges, des écarts beaucoup plus petits que ceux qui ont été trouvés par Miss Trew et Dr. Spencer. En outre, Ranganadham s'étonne que pour les mélanges d'acétone-chloroforme la courbe donnée par Miss Trew et Dr. Spencer passe de la région diamagnétique à la région paramagnétique.

Les deux physiciens anglais ont répondu à ces observations[3] et annoncent la publication prochaine de leurs mesures sur les mélanges acétone-trichloréthylène et bromoforme-acétone.

Je voudrais qu'il me fut permis de rappeler ici deux autres mémoires sur les susceptibilités magnétiques des mélanges liquides. Déjà, en 1918, Alpheus W. Smith et Alva W. Smith[4] ont mesuré les susceptibilités magnétiques des mélanges suivants : acétone-eau, acide acétique-eau, acide acétique-benzène, acétone-alcool éthylique, et pour ces quatre couples de mélanges les courbes qui donnent la susceptibilité magnétique en fonction de la composition sont des droites. Cependant pour les mélanges d'acétone et d'eau, qui se forment avec une contraction très grande du volume, il se produit un maximum d'indice de réfraction ainsi qu'on le lira dans mon mémoire.[5] On verra aussi dans ce mémoire que l'on sait depuis longtemps que les solutions dans l'eau de l'acide acétique donnent lieu à des maxima de densité et d'indice de réfraction.

Enfin, en consultant le volume VII, années 1925–1926, des " Tables annuelles de constantes et données numériques " (Marie), partie concernant l'électricité et le magnétisme, p. 1014, nous voyons que Trifonov, en 1924, s'est occupé de la même question et a étudié les mélanges suivants : benzène-métaxylène, benzène-sulfure de carbone, acétone-chloroforme, benzène-nitrobenzène, benzène-tétrachlorure d'étain, acétate d'éthyle-tétrachlorure d'étain.

Pour aucun de ces couples de liquides on ne trouve un maximum de la susceptibilité magnétique et aucun des mélanges d'acétone et de chloroforme n'a été trouvé paramagnétique.

Ce rappel de travaux antérieurs montre avec quel intérêt les physiciens prendront connaissance du mémoire annoncé par Miss Trew et Dr. Spencer. Cependant, vu la discordance entre les résultats obtenus, on peut déjà affirmer que la mesure des susceptibilités magnétiques ne doit pas être recommandée comme une méthode d'investigation sûre de la constitution des mélanges liquides.

Measurements of the Height of a Large Drop of Mercury.

IN determining the surface tension of mercury and other liquid metals, many workers have used the method of measuring the height from the maximum section to the summit of a large drop. Most agree as to the method of setting on the maximum section, but a variety of ways are used to define the top of the drop. Two recent papers[1] describing measurements made after using every care to obtain pure mercury and high vacuum, and with no essential difference in technique except in the method of defining the summit of the drop, give respectively 515 ± 6·8 dynes and 432·2 ± 0·3 dynes for the maximum surface tension of mercury at 31° C. In view of this discrepancy and the fact that it corresponds to a difference of only about 0·2 mm. in height of the drop, the following notes on methods tried out in this laboratory may be pertinent.

(1) A collimated beam of light from a small distant source set carefully at the height of the drop shines over the summit, and the top of the drop is seen in the horizontal microscope, accompanied by diffraction lines. The definition is good, and the very small correction for diffraction can be determined by setting on to a similarly disposed mercury drop in the open laboratory, when the exact surface may be located by bringing a spherometer point almost into the surface and taking readings on both point and reflection.

(2) A card ruled with slanting lines is placed behind the drop and the setting is made on the intersection of the lines and their reflection.[2] The definition is sharp, but, of course, the telescope must be focused on the card and not on the drop, and there is thus a considerable horizontal distance between the points, the vertical separation of which must be measured. This increases any error due to inaccurate levelling, and, if the aperture is small, it is not easy to see reflections from a horizontal surface using a truly horizontal telescope.

(3) If the drop is enclosed in a box and light admitted through a ground-glass window on one side while observing through a window on the opposite side of the box, the drop appears as a sharply defined black body. What appears to be the upper surface of the drop, however, is really the lowest curve on the drop which will reflect rays coming from the top of the ground-glass window so that they pass into the telescope. The position of this curve depends on the size of the drop and its position relative to the top of the window. Using a window 4 cm. from the centre of a drop 6 cm. in diameter, the following readings were taken as the window was blackened out strip by strip from the top downward:

Height from top of drop to top of window.	Reading of microscope set on apparent top of drop.
1·0 mm.	3·343 mm.
2·2 ,,	3·328 ,,
5·1 ,,	3·274 ,,
8·3 ,,	3·222 ,,

The setting on the top of the drop, using method (1), was 3·367 mm., and the correction for diffraction about + 0·01 mm. M. Kernaghan uses an enclosed drop and a ground-glass window, but the method of defining the summit is not very clearly stated. It is remarkable that the difference of 83 dynes quoted above is in the direction to be expected if the workers had used methods (2) and (3) respectively without completely eliminating the sources of error mentioned.

In spite of individual workers obtaining consistent values, the question of the value of the surface tension of mercury in vacuum remains unsettled, and it is obviously desirable that workers should check their readings for the top of the drop by using two distinctly different methods of illumination and finding if the setting is unaltered. It may be said that measurements made here, both with glass and using an apparatus entirely of fused silica made by the Thermal Syndicate, indicate a greater height for the drop than those recorded by M. Kernaghan.

Polarity and Vapour Pressure.

IN considering the effect of polarity on the vapour pressure and association of a liquid, a simple case is its influence on the partial vapour pressures of a polar liquid in its binary mixtures with a non-polar liquid, which, except for lack of polarity, should preferably be closely related in chemical structure to the polar liquid.

It is convenient to consider as 'perfect' a solution in which the restraining force on a polar molecule about to be vaporised is the same as in an infinitely dilute solution of the polar in the non-polar liquid. Perfect solutions are then represented by the tangent to the partial vapour pressure curve of the polar liquid at the limit of zero concentration. It is proposed to consider the effect of polarity in producing deviations from this tangent. To take deviations from Raoult's law as measures of imperfection is unsatisfactory, since to do so implies that all pure liquids are perfect, whilst admitting that mixtures of liquids may be imperfect.

Let the activity of the polar liquid be equal to b times its vapour pressure. Then in a perfect solution the free energy (F_i) of the polar liquid per molecule is $kT \log_e bp_i$, where p_i is the partial vapour pressure of the polar liquid, and k is Boltzmann's constant. Let the partial vapour pressure of the polar liquid in a solution of the same concentration in reality be p: the corresponding free energy (F) being $kT \log_e bp$. The free energy of transference of a molecule from a perfect to a real solution of the same concentration is $F - F_i = kT(\log_e bp - \log_e bp_i)$, that is

$$\frac{p}{p_i} = e^{(F - F_i)/kT}.$$

For such a dipolar molecule as is under consideration, F may be identified with the energy due to the field of the dipole in a medium of dielectric constant equal to that of the real solution of the concentration involved. Similarly F_i is the energy in a medium of dielectric constant equal to that of the pure non-polar liquid (since under perfect conditions the environment of a polar molecule remains the same as in an infinitely dilute solution in the non-polar liquid). If the polar molecule be treated as two charged spheres in contact with each other, for simplicity assuming that each sphere is completely immersed in the dielectric and integrating up to a sphere, the radius of which may be called the molecular radius, it has been shown[1] that this energy is given by $\mu^2/3a^3D$, where μ is the dipole moment, D is the dielectric constant, a is the molecular radius. Therefore

$$\frac{p}{p_i} = e^{-\frac{\mu^2}{3a^3kT}\left(\frac{1}{D_i} - \frac{1}{D}\right)}.$$

Unfortunately the data required to test this relation are very scanty. The values of a necessary to give the observed values of p/p_i for heptane-ethyl iodide mixtures at 50° are given below (data by Smyth and Engel[2] and Smyth and Stoops[3]):

Mol. Fraction C_2H_5I.	Observed Partial Vapour Pressure C_2H_5I (mm.).	Ideal Partial Vapour Pressure C_3H_5I (mm.).	$\frac{1}{D_i} - \frac{1}{D}$	a (Angstrom Units).
0·1	57·3	58·8	0·0574	1·06
0·2	107·5	118·5	0·1089	1·28
0·3	151·7	178·5	0·1557	1·41
0·4	188·3	238·3	0·1982	1·50
0·5	218·0	297·8	0·2384	1·56
0·6	243·8	357·5	0·2749	1·61
0·7	268·0	417·5	0·3080	1·65
0·8	292·8	477·5	0·3379	1·68
0·9	321·0	537·5	0·3643	1·72
1·0	354·5	598·0	0·3866	1·75

These results are promising, and experimental work is now in progress with the object of testing this point of view further.

Atomic Hydrogen Occluded in Iron Nitride.

ATOMIC hydrogen in iron has so far been known to be occluded when iron is quenched from a high temperature in water or when iron is electrolytically deposited. I have observed the existence of atomic hydrogen in iron nitride prepared by heating iron in the current of ammonia gas. I confirmed it by measuring the single potential of the iron nitride in normal ferrous sulphate solution. The time voltage curve of the iron nitride showed a minimum due to atomic hydrogen at the beginning, similar to that which appeared in the curve of iron quenched and loaded with atomic hydrogen, obtained by T. W. Richards.[1]

I also confirmed the existence of atomic hydrogen by immersing the iron nitride in a solution of potassium ferricyanide and observing the formation of Prussian blue on adding the ferric chloride solution. This reduction, $K_3Fe(CN)_6$ + atomic hydrogen $\longrightarrow K_4Fe(CN)_6$, also takes place with the iron quenched in water, and thus loaded with atomic hydrogen, but never with ordinary iron.

Audibility of the Aurora Polaris.

IT cannot be doubted that many persons have heard a distinct sound when watching a brilliant display of aurora. Naturally they have connected the two phenomena and have assumed that the sound was emitted by the aurora. Communications regarding the auroral sound appear now and then, and recently Mr. J. H. Johnsen has collected a great number of reports on the auroral sound in his pamphlet, "Concerning the Aurora Borealis", which has been reviewed in NATURE by Prof. S. Chapman.[1] Examining these reports, one finds that the auroral sound, with few exceptions, is described as a weak but distinct swishing or hissing sound which is heard during auroral displays on calm nights and at low air temperatures. I wish to emphasise the fact that the air temperature, in the cases in which it is stated, ranges between −35° F. and −50° F.

Very few investigators of the aurora admit that the sounds which have been heard can be ascribed to the aurora, but a satisfactory explanation of the observations is not yet commonly known, in spite of the fact that such an explanation has been given by Roald Amundsen in his book "The South Pole". Amundsen says (in translation from the original Norwegian edition, p. 417): "The swishing aurora does not exist. What one hears is one's own breath which freezes in the cold air".

The 'swishing breath' is a phenomenon which is well known to many arctic travellers and to natives, but it has not often been mentioned in the scientific literature. J. v. Hann[2] quotes observations of the 'swishing breath' from Siberia, and A. Wegener[3] has discussed the phenomenon, which he has observed in Greenland at temperatures below −44° F.

From my own experience, I can confirm that when the air temperature is below −40° F. and calm prevails, one hears a swishing or hissing sound when exhaling, possibly because the water vapour of the breath immediately condenses to ice crystals which collide when falling to the ground. The sound of the freezing breath is very distinct but weak, and is, therefore, heard only when the observer is standing still and listening intently. The phenomenon is very puzzling to an unexperienced observer, and if several persons are standing together it is impossible to become aware of the real cause of the sound. In that case the sound naturally is connected with any conspicuous phenomenon which occurs simultaneously, for example, an aurora. In the arctic the sky is generally clear when the temperature is low and the air is calm, and in the zone of maximum auroral frequency an auroral display is seen on nearly every clear night. An observer standing still and watching a brilliant display then hears a weak swishing sound, rising rhythmically, and naturally he assumes that this sound is emitted by the aurora.

I do not claim that the sound which has been ascribed to the aurora was always the sound of the freezing breath, but I am convinced that such has been the case in by far the greater number of instances in which persons report having 'heard the aurora'. It would be of interest to study more closely the conditions at which the sound of the freezing breath is heard, and also to direct the attention of auroral observers to the phenomenon in order that in the future the swishing breath is not interpreted as 'auroral sounds'.

The Harvard Museum Expedition to Australia.

THE announcement made by *Science Service*, and commented upon in NATURE of July 11, evidently gives a misleading idea of the objects sought by the Harvard Museum Expedition to Australia. It is not primarily an expedition to secure specimens for a museum, but for the study of the animals of the region when alive. Such work necessarily entails the killing of a limited number of forms, so as the better to understand their habits, feeding, movement, reproduction, and so on. But the 'bag' thus sought is trivial and not to be compared to the long series valued by philatelists and many former collectors of animals and plants. The idea of vastly long series is dead so far as modern zoological museums are concerned, owing, amongst other reasons, to the fact that the public will not endow them sufficiently for such ends.

The museum at Harvard was built by Alexander Agassiz in memory of his father, Louis, these two of our greatest exponents of field work of the last century. It contains their collections, which are relatively small, although of enormous importance. Around them has been built what is essentially a teaching and research institution. The Louis Agassiz Museum is weak in Australian animals and doubtless would desire to complete its series, but it would obviously be more economical and efficient to order the specimens required from Australian dealers. This, however, in mammals, would not suit Glover Allen, who complains bitterly of his teaching handicap in never having himself seen the great marsupials in their own country.

The leader of the Harvard Expedition is W. M. Wheeler, one of the greatest of American zoologists, formerly director of the Bussy Institute, and now attached to the Agassiz Museum. His name is quite sufficient to guarantee the character of this expedition, for he is one of the makers of modern scientific entomology, the dominant theme of which is the living insect. Also attached to the museum is Dr. Jackson, who has travelled widely in his studies of the fossil and living echinoderms in respect to their mode of life. On this side the Agassiz Museum recently sent an expedition to North Australian waters under Dr. H. L. Clark, to study them and other marine bottom-living invertebrates in their natural environments; this is also a side-line of the present expedition. The director of the Museum is Tom Barbour, a real naturalist, his speciality being the reptiles of America, which he has sought in all their haunts. Fisheries and oceanic biology centre in the living animals and plants, and are represented by Henry B. Bigelow, director of the new Oceanographical Institute at Woods Hole. It is useless to extend a list where one and all the staff have that field experience that is so necessary to give life to great museums. All take their share in teaching in the Harvard School of Biology, in which Profs. Parker and Crozier are dominant personalities, eminent in their experimental studies of living matter.

Training of Colonial Probationers in Anthropology.

IN 1930–31, the scheme arranged by the committee charged with the training of Colonial (African) probationers at Cambridge, provided forty hours lectures which were obligatory and twenty hours for optional consultation. My colleagues, Mr. R. U. Sayce and Mr. J. H. Driberg, have experience of African conditions and personal knowledge of administrative problems in Africa. For 1931–32, the Colonial Office has approved of an additional course of eight lectures on the principles of African customary law. Other subjects—languages, criminal law, Mohammedan history, evidence and procedure, common law, agriculture, phonetics, history, and geography—have to be provided for in the Michaelmas and Lent Terms, so that under present conditions the allotment to anthropology is as large as we can hope for. If the conditions change, we shall press for more, and even now are ready to provide more. There are other features in the scheme which I regard as needing modification, and hope that argument and persuasion will prevail in the long run.

I must also record the fact that early in the year we were asked to receive two officers for study leave and readily agreed to do so, subject to our existing commitments. One of them came to Cambridge and the other preferred London, and I have no reason to suspect that pressure is brought to bear upon officers to choose Oxford or Cambridge in preference to London for study leave. In Cambridge we do the best we can for them. We welcome them gladly, and—speaking for myself—we learn much that is important and interesting from them.

The External Meatal Notch as a Primitive Character.

THE majority of the many racial variations of the human tympanic bone result from the differing degrees of development of the lateral extensions of the annulus tympanicus. These lateral extensions typically develop as anterior and posterior elements which, by uniting at their ventral margins, complete the floor of the meatus acusticus externus.

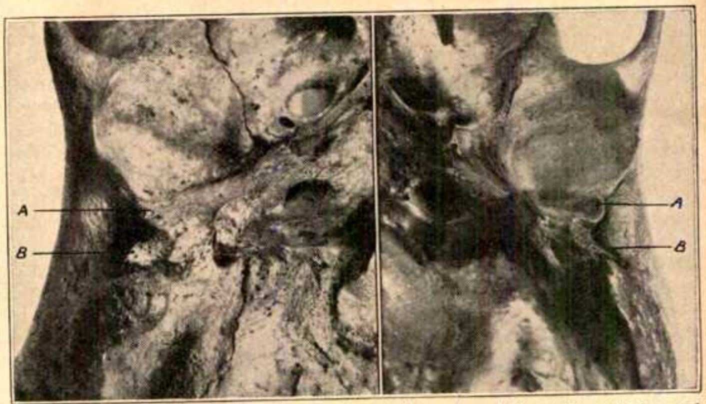

FIG. 1.—Tympanic region of two Australian skulls. *A* and *B* are the anterior and posterior tympanic moieties separated by the external meatal notch.

Failure of union of these two processes at the median end of the tympanic plate results in the persistence of the foramen of Huschke. Such failure of union in the adult may be as frequent as 32 per cent in some racial series. Failure of union at the outer extremity of the bony meatus, though producing a characteristic condition, appears to have had but little, if any, attention devoted to it. When this failure of union occurs, the auditory meatus itself consists of an anterior tympanic moiety and a posterior moiety, separated by the *external meatal notch*.

This external meatal notch is of very frequent occurrence in Australian skulls, and two examples are shown in Fig. 1.

Failure of ventral union of the anterior and posterior moieties of the tympanic plate may therefore result in (1) a persistent foramen of Huschke, so frequent in the skulls of Chamorros, (2) persistent external meatal notch, such as is frequently present in the Australian, or (3) a continuous deficiency, such as characterises the normal child at about its second year, and persists in the adolescent skull of *Sinanthropus*.

Class Distinction in the Society Islands.—A study of traditional history and political grouping in the Society Islands, by Dr. E. S. Craighill Handy (*Bull.* No. 79, Bernice P. Bishop Museum), is devoted to the elucidation of the ethnic and cultural relations of the *manahune* (landless commoners) who dwelt mostly in the interior of Tahiti in the days prior to the breaking down of class distinctions by the missionary system. A preliminary investigation had indicated that they represented a survival of an earlier population that had been conquered and pushed back by the ruling dynasty, the *Hui Arii*, who were supreme in all the islands when they were discovered by Europeans. The customs and traditions of this invading dynasty were of an entirely different order from those of the earlier tribal culture. The *manahune*, who were the most numerous element in the population, were the serfs of the *arii* (feudal lords) and their supporters the *raatira* (landed proprietors). They were the wood-cutters for the royal family, the high-priest, and the warriors, the pickers of taro leaves, the fishers of eels and freshwater fish. Of the two types of house, the rectangular and the apsidal, the former belongs to the earlier culture. The *manahune* were valley-dwellers, cultivating the taro and sweet potato on irrigation terraces. The warriors' house was probably their central social and political institution, and the chief cause of war was blood-revenge. Human skulls and jawbones were preserved and reverenced. Tane, Roo (Rongo), and Tu were worshipped as patrons of woodcraft, agriculture, and war respectively. On the other hand, among the *Arii* the furniture and domestic utensils of their apsidal houses were supported on legs, their boats were composite built-up vessels, and they were distinctly maritime and not agriculturists, excelling in sea fishing which was a royal sport. They wore the *pareu*, the short skirt, as opposed to the loin-cloth, and made fine mats, used for articles of clothing and other purposes. Their outstanding contribution to Tahitian religion was the god Taaroa, their ancestor, who assumed the position of creator and supreme god of the local cult.

Pottery of Ancient Mexico.—A study of certain characteristics of the pottery of ancient Mexico, referring particularly to the types and distribution of decorative motives on specimens in the Museo Nacional of Mexico, is contributed by Sr. Eduardo Noguera to the *Journal de la Société des américanistes de Paris*, N.S., t. 22 (fasc. 2). Taking the collection as a whole, without reference to cultures, 39·7 per cent of the pottery vessels showed no decoration, the next highest percentage being shown by those with geometric motives, 27·7 per cent; anthropomorphic motives came next with 19·7 per cent. Of the pottery objects, other than vessels, in the collection, 89 per cent were anthropomorphic, 5·6 per cent zoomorphic, and 4·1 per cent skeuomorphic. When the cultural grouping is taken into account, the Aztec pottery showed the highest percentage of decorated ware. It also showed the highest percentage with geometric decoration. It is suggested that this preponderance of geometric motives is due to the fact that in other cultures decorative art developed through the stylisation of a realistic symbolism. The small number of skeuomorphic motives is attributed to the relatively backward stage of industrial development. Here again the predominance in Aztec art is due to the later and more developed stage attained by the Aztecs before the Conquest. The low percentage of phytomorphs is noticeable, and may be due to the fact that the geographical zones occupied by these cultures were of a relatively high altitude and vegetation was not so luxuriant as in the coastal regions. It is possible that a study of Maya and Huaxtec pottery on these lines would show a high percentage of phytomorphs to correspond with the more abundant vegetation of their habitat. Following the same line of argument, it may be shown that the Toltec and Aztec potteries are inferior in the percentage of zoomorphs to the Zapotecan, Mixtecan, and Tarascan cultures, owing to the fact that the two former inhabited the Valley of Mexico, in which animals were less abundant than in the habitat of the latter.

Detection of Syphilis.—In a paper presented in the *Rendiconti della Reale Istituto Lombardo di Scienze e Lettere* (parts 6-10), Dr. L. V. Blina gives the results of the application of the Wassermann and Kahn reactions to 650 samples of blood sera from syphilitic and non-syphilitic patients. In a number of cases of syphilitic infection, the Kahn procedure reacted positive and the Wassermann procedure negative, and the tendency to give negative indications as a result of therapeutic treatment proved less pronounced with the Kahn than with the Wassermann reaction. The former reaction reaches its highest degree of positivity for secondary syphilis and often shows negative with the tertiary form. These experiments are in favour of the Kahn reaction as a means of detecting syphilis, and the simpler technique and more rapid execution of this reaction give it an added advantage over that of Wassermann.

Mimicry in Indian Butterflies.—The Punjab University proposes to publish in the *Bulletin of the Department of Zoology*, of which the first part has reached us, a series of papers devoted to an intensive study of the fauna within a radius of five miles of Lahore. The first contribution, by Dev Raj Puri, deals with the butterflies, which, probably because of the extremes of climate in the summer and winter months at Lahore, are abundant only during August, September, and October. Keys and descriptions are given for the identification of families, genera, and species, and these are supplemented by thirty excellent coloured figures. In such a work, however, the lengthy synonymy of specific names is unnecessary, and since it occupies as much space as the essential descriptions, it might be drastically reduced. The author observed several new examples of protective coloration and mimicry. In *Melanitis leda*, always found resting on dry bamboo leaves under bamboo trees, the undersides of the wings resembled the colouring of the leaves. *Junonia orithya*, a common species, has wings of brilliant colour, and in rest the colours are exposed on the spread wings, but on the approach of danger the wings are folded up and only the obscure dust-coloured undersides exposed. *Pareronia hyppia* and *Delias eucharis* females resemble each other and occur together, but since the former was always entire, while the latter had sometimes the edges of the wing torn by birds, the former would appear to be distasteful and the model. Another suggested case of mimicry is that between the female of two species of Pieridæ, *Huphina nerissa* and *Ixias pyrene*.

The Evolution of the Excretory System in Cercariæ.—Lieut.-Col. R. B. Seymour Sewell (*Rec. Ind. Mus.*, 32, part 4, Dec. 1930) discusses the evolution of the excretory system in certain groups of furcocercous cercariæ. A study of the evolution and development of this system tends to show that every flame-cell pattern (that is, the number and arrangement of the flame-cells) is reached by the division of an original single-pair flame-cell system. Such a system is known only in certain miracidia: for example, of *Amphistomum, Fasciola, Gastrodiscus, Gorgodera*. The next stage in evolution is represented by the excretory system of the miracidia of the genera *Holostomum* and *Schistosoma*, in which the originally single flame-cell of each side has divided into two, so that four flame-cells altogether are present. A further division of each of these flame-cells would give four flame-cells on each side of the body, and it is such a system that seems to be the starting point in several different lines of evolution in the furcocercous cercariæ. This is the condition in the schistosomes, in which there are four pairs of flame-cells, three pairs in the body of the cercaria and the fourth in the tail-stem. The author, starting from this condition, traces the different modes of division of the flame-cells and of the grouping of the flame-cells so produced, dealing first with cercariæ which are apharyngeal and brevifurcate and then with those which are pharyngeal and longifurcate. This last series is subdivided into three groups. While recognising the difficulty of constructing a classification of the fork-tailed cercariæ based only on the excretory system, Lieut.-Col. Sewell is convinced that this system is the most important for the correct determination of the systematic position of any given species in the evolutionary series. The paper contains helpful diagrams illustrating the different modes of derivation from four flame-cells of the systems exhibiting five to twelve flame-cells, and the probable lines of evolution of the principal forms.

Chromosome Linkage in a Triploid *Œnothera*.—The triploid *Œnothera pycnocarpa*, which was supposed by Catcheside to have a ring of twenty-one chromosomes, has now been re-studied by him (*Jour. of Genetics*, vol. 24, No. 2) and a variety of arrangements found in diakinesis. This is the most detailed study that has yet been made of the diakinesis stage of meiosis in a triploid *Œnothera*. The great variety of linkages found is in harmony with the great range of genetic types, including many trisomic mutations, known through the work of de Vries to be obtained from triploids when selfed. As an example of the conditions, one nucleus is found to contain four ring pairs of chromosomes, two rod pairs, three univalents, one Y-shaped trivalent and a chain of three. Another contains five univalents, a chain of six, and a chain of eight with two attached to one of its ends. All the groupings, with one possible exception, conform to the segmental formula proposed, and are in harmony with the view that the chromosome linkages have originally arisen by crossing of species, followed by rearrangements of segments of the chromosomes.

Eocene Mollusca of North-west India.—A memoir on the molluscan fauna of the Laki and basal Khirthar Groups by L. R. Cox (*Trans. Roy. Soc., Edinburgh*, 57, pp. 25-92, pls. i-iv ; 1931) is based mainly on a collection made in recent years by Lieut.-Col. L. M. Davies, but the author has also studied the material collected by earlier geologists, from 1834 onwards, with the important result that the horizons of most of the species described in the great work by d'Archiac and Haime (1853–54) can now be fixed. The fauna is of Ypresian age and includes nearly a hundred species of gasteropods and lamellibranchs. The Laki fauna is very distinct from that of the underlying Upper Ranikot beds, but this is due partly to difference in the facies of the deposits. On the other hand, there is no great difference between the faunas of the Laki and Khirthar groups. A considerable number of the species, especially of the gasteropods, are confined to India, and those with a wider range are mainly limited to the Tethyan province. A few, however, are found in the Eocene of Europe, and one even in Jamaica.

Jointing and Tectonics of the Craven Area.—In the *Quart. Jour. Geol. Soc.*, 1931, pp. 392-421, L. R. Wager describes the jointing of the Great Scar Limestone of Craven and its relations to the tectonics of the area. The joints fall into two sets that are nearly at right angles to each other and fairly constant in direction. They are interpreted as shearing fractures due to a maximum horizontal compression in an approximately north-west–south-east direction. The jointing was produced in the early part of the interval between the Coal Measures and the Permian, and is contemporaneous with the Dent Fault, the North and Middle Craven Fault-systems, and the folding in South Craven. The North Craven Fault-system is a tear-fault, and the drag due to the relative horizontal movement has caused a local modification of the joint directions in the neighbourhood of the fault. The deep burial of the pre-Carboniferous floor in South Craven and the shallower burial of this floor in North Craven are responsible for the different reactions of the two areas to the Hercynian compressive forces. Renewed sinking of the South Craven area took place in post-Permian times, partly along the early faults and partly along newly initiated faults which followed one or other of the directions of jointing.

Photographic Vibrograph.—Messrs. Askania-Werke A.-G. Bambergwerk, Berlin-Friedenau, Kaiserallee 87-88, have issued a pamphlet (Geo. 105E) describing their latest pattern vibrograph. The instrument, which consists of two units joined by a light-tight tube, employs a photographic recording system. One unit comprises the camera, utilising 6 cm. wide bromide paper and a 4-volt lamp for illumination. Various paper speeds are obtainable, and short lengths of record can be cut off with a knife and removed in daylight for subsequent development. The vibrograph proper is normally constructed so that all three components of motion, vertical and two horizontal, are recorded side by side on the paper. Instruments can also be supplied which record only two or one of the components. The natural frequency of the units is stated to be five cycles/second, a value sufficiently low for most practical work on roads and in buildings, and variable liquid damping is provided. A useful feature is an arrangement whereby the mechanical magnification of the instrument can be altered in the ratio of ten to one. In addition, a choice of three lenses is available, thus permitting in all a choice of six values of magnification, varying from 125 to 3000 times.

Atomic Weights Deduced from Mass-Spectra.—Some new values for the atomic weights of a number of elements are given by Dr. F. W. Aston in an account of an investigation of their mass-spectra which appears in the August number of the *Proceedings of the Royal Society*. In the majority of cases these agree with the accepted chemical values. Amongst these is rhenium, which is perhaps of particular interest, Dr. Aston's value being 186·22 ± 0·07 and Honigschmid's 186·31. For the three elements selenium, tellurium, and osmium, there are, however, serious discrepancies ; the atomic weights found by the mass spectrograph for these are 78·96 ± 0·04, 128·03 ± 0·1, and 190·31 ± 0·06 respectively, against chemical values of 79·2, 127·5, and 190·9. It remains to be seen if the chemical values are actually inaccurate, but it will be recalled that in two other instances—krypton and xenon—more recent redeterminations by classical methods have tended to support the validity of the values found electrically.

Conductivity of Tetraethylammonium and Ammonium Salts.—The August number of the *Proceedings of the Royal Society* contains some data for the conductivity of various ammonium and tetraethylammonium salts in methyl alcohol, which have been obtained by Sir Harold Hartley and a number of collaborators. The measurements were made at 25° C. and show the rather curious result that the mobility of the complex ethyl ion (NEt_4^+) is seven per cent greater than that of the relatively simple ammonium ion (NH_4^+). With a single exception, the results for the eleven salts studied agree with the prediction of the Debye theory of electrolytes that the molecular conductivity should change in a linear manner with the square root of the concentration; the rate of change of conductivity with concentration also affords evidence for the essential accuracy of some recent developments of Debye's theory, observed and calculated values of the rate of change agreeing on an average to within twenty per cent. The general trend of the results, and particularly the behaviour of the good conductor tetraethylammonium perchlorate, indicates that the magnitude of the deviations from theory increases with the speed of the ions present.

Insulin Therapy.—Although our knowledge of the mechanism of the action of insulin in the body is very incomplete, there is no question of its value in the treatment of diabetes mellitus. The principles of its practical use are well defined, although the actual details may vary; in every case it is necessary to ensure a balance between the diet and dosage of insulin, such that the blood-sugar is kept within normal limits and none is excreted in the urine. The amount of insulin required will naturally vary according to the severity of the disease and the amount of food taken. The details, which vary according to the physician in charge of the case, are concerned with the methods of determining the amount of insulin required and of calculating the diet. A convenient account of the treatment of diabetes with insulin is given in a small brochure recently issued by the manufacturers of "A.B." Brand Insulin (British Drug Houses, Ltd., and Allen and Hanburys, Ltd.). Simple methods for estimating sugar in blood and urine are described, as well as a simple dietary scheme. The practical use of insulin is given in detail. Sections are devoted to the treatment of the various conditions which may complicate the disease. Although insulin rarely cures, it can undoubtedly prolong life when properly employed; a cure can only be expected when the affection of the pancreas passes off without damaging the organ permanently. In such a case insulin may tide the patient over the infection and permit of recovery of function by the gland. In many cases, however, the timely use of insulin may promote a definite improvement in the condition of the pancreas. In all, its use permits of a better dietary being prescribed, with greater comfort to the patient. Insulin has also found a use in the treatment of various nondiabetic conditions: it is employed to improve the metabolism of carbohydrate, and may be used in states of malnutrition and when it is advisable to stimulate the metabolism of these food-stuffs, as in various forms of vomiting and in liver affections. The booklet may be recommended to those in search of a short and readable account of insulin treatment, based on selected excerpts from current medical literature.

Astronomical Topics.

A Daylight Meteor.—A brilliant meteor was observed by Mr. J. R. Clarke, University, Sheffield, just before sunrise, from Loch Doon, Ayrshire, on Aug. 26 at about 4^h 15^m G.M.T. It travelled from west to east with very low apparent velocity, and was visible for about half a minute. No other reports are to hand at present.

Stellar Photometry.—Some years ago the photographic magnitudes of stars in the zone +90° to +73° declination were obtained by Parkhurst at Yerkes, and this work has now been continued by A. S. Fairley at the same observatory over the zone +75° to +60°. The method used is that of extra-focal images, obtained 6 mm. inside the focus of a Zeiss 14·5 cm. doublet of 81 cm. focal length. A series of fourteen accurately graded artificial images was impressed on each plate before development, thus providing an independent scale for the comparison of densities, which were measured in a Hartmann microphotometer. The zero point was calculated for each plate from stars in the Potsdam Photometric Durchmusterung, the magnitudes of which were first corrected for colour index (assumed from spectral type) and then reduced to the international scale. The methods employed are described in the *Astrophysical Journal*, vol. 73, p. 125, in which Fairley gives the resulting photographic magnitudes of 2354 stars down to magnitude 8·25 within the above-mentioned zone.

The Apparent Recession of the Spiral Nebulæ.—*Leaflet* 37 of the Astronomical Society of the Pacific gives an account by Mr. Milton L. Humason of the methods now adopted at Mount Wilson of measuring the radial velocities of the distant spiral nebulæ. A new spectrograph lens, designed by Dr. W. B. Rayton, has been brought into use, which greatly shortens the exposures; these, however, still have to be continued on several successive nights in the case of the fainter nebulæ. The photographic plates measure $\frac{5}{8}$ inch by $1\frac{1}{2}$ inch, and the length of the spectrum varies from $\frac{1}{25}$ inch to $\frac{1}{12}$ inch, according to the prisms used.

Up to three years ago the measures of distance extended up to 6 million light-years; they now reach 105 million. Reasons are given for assuming that the smaller and fainter nebulæ are the more distant, and it is then shown that these small faint nebulæ have also the largest velocities of recession. The question whether the recession is real, or arises from the properties of space, does not affect the use of the shift to the red as a measure of distance.

A photograph, taken with the 100-inch reflector, is reproduced, showing a group of faint nebulæ in Leo. The brightest of these is of magnitude 15·5, and is stated to be the faintest and most distant object for which a measurable spectrum has been photographed. The deduced distance is 105 million light-years, and the measured recession is 12,000 miles per second, or $\frac{1}{15}$ of the velocity of light.

Measures are given of seven other nebular groups, in which 30 nebulæ were examined. The results show that the distances estimated from apparent brightness and diameter are in excellent agreement with those deduced from the velocities of recession. So far as the results extend at present, they indicate a fairly uniform distribution of nebulæ in different regions of space.

The Nature of Cohesion.*

LIKE all other branches of physics, the subject of cohesion has been profoundly modified by the advent of wave mechanics. When atoms were regarded as miniature solar systems, there was no mathematical machinery capable of dealing with their mutual interaction. But now the outlook is different. There is no attempt in wave mechanics to follow the life-history of electrons in atoms. Rather does it give a statistical average of their distribution in space, from which may be inferred the probability that an electron may be found here or found there. Mathematically, if not physically, electrons in atoms are smeared out. Where once was thought a solar system played, is now a shimmering haze.

Wave mechanics does not give the density of these charge distributions directly. It gives instead, when only one electron is being considered, a quantity ψ, called a wave function, which may be real or complex, and the density ρ of the electron distribution is equal to the square of the modulus of ψ or to $\psi\bar{\psi}$. The quantity ψ is a function of the co-ordinates of the electron, and these are four in number, three being necessary to specify its position in space, and the fourth its direction of spin. The probability of finding the electron in an element of volume $d\tau$ is $\rho d\tau$.

When there are several electrons in an atom, its configuration may in an approximate theory be specified by a number of wave functions, $\psi_\alpha, \psi_\beta, \ldots \psi_\nu$, each a function of the four co-ordinates of an electron. For a reason not yet understood, Nature places a restriction on the choice of these wave functions: no two of them may be the same. This exclusion principle, first enunciated by Pauli, seems to be of very general validity in physics, and, in particular, accounts in a very remarkable way for many of the observed properties of atoms and molecules.

If one of the electrons, say electron 1, were alone, the probability of finding it in an element of volume $d\tau_1$, would be $\bar{\psi}_\alpha(x_1)\psi_\alpha(x_1)d\tau_1$ or $\rho_\alpha(x_1)d\tau_1$, where x_1 denotes its four co-ordinates. Similarly the probability of finding electron 2 in an element of volume $d\tau_2$, if it were alone, would be $\rho_\beta(x_2)d\tau_2$. It might be supposed that the probability of finding an electron in $d\tau_1$, another in $d\tau_2$, and so on, simultaneously, were the product of these separate probabilities, namely, $\rho_\alpha(x_1)\rho_\beta(x_2) \ldots d\tau_1 d\tau_2 \ldots$ But this result is not true. It is untrue because an important principle has been ignored, namely, that all electrons are identical and that interchanges of the electrons may occur without observable effects. Electron 1 may be associated with wave function ψ_β, or in fact with any of the set of wave functions ψ_α to ψ_ν. The correct expression for the probability may, in certain cases, be expressed quite simply, as has recently been shown by Dirac. It is $\rho d\tau_1 d\tau_2 \ldots$, where ρ is a determinant of N rows and columns, a typical term of which is $\rho(x_i, x_k) = \Sigma_\alpha \bar{\psi}_\alpha(x_i)\psi_\alpha(x_k)$. This determinantal form for ρ contains the expression given above as its leading term, but there are many other terms not previously given by an atomic theory.

The probability of finding an electron in $d\tau_1$ independently of the position of all other electrons is then obtained by integrating ρ over the co-ordinates of all the electrons except one, and may be shown to be $\Sigma_\alpha \rho_\alpha(x_1)d\tau_1$. This expression is the sum of the densities of the probability patterns of the separate electrons, and, moreover, contains the co-ordinates of one electron only, so that, apart from the spin co-ordinate it may be represented in ordinary three dimensional space. It justifies us in constructing a picture of an atom by superimposing the patterns of the individual electrons of which it is composed. Such pictures are very instructive and have been used in a variety of ways with striking success. One important result is that the distribution of electron density in the inert gases and, indeed, in many other atoms is spherically symmetrical, and so the early pictures of them as minute spheres are to some extent justified. The halogen atoms, on the other hand, are not spherical. They are like the familiar meteorological forecast, "Unsettled, with bright intervals".

The importance of the new form for the probability function ρ becomes evident when calculations are made of the *energy* of electronic systems. Electrons exert electrostatic forces on each other and the average value of the electrostatic energy can only be calculated when we know the probability that any pair of electrons will be at a specified distance apart. A detailed calculation of the energy of an atom or the interaction energy of two atoms depends then very closely on the probability function ρ.

The probability of finding two electrons in specified places independently of the other electrons proves to be $\{\rho(x_1, x_1)\rho(x_2, x_2) - \rho(x_1, x_2)\rho(x_2, x_1)\}d\tau_1 d\tau_2$, with the definitions of $\rho(x_1, x_2)$, etc., already given. The mutual energy of two electrons consists then of two terms; the first is the average of $(e^2/r)\rho(x_1, x_1)\rho(x_2, x_2)$ integrated over the whole space of electrons 1 and 2; the second is the average of $(e^2/r)\rho(x_1, x_2)\rho(x_2, x_1)$. Apart from certain terms of these expressions which cancel, the first represents the Coulomb interaction of the individual distributions of electric charge ρ_α, ρ_β, etc. This may be called the *Coulomb energy*.

The second term in the above expression is new. It has proved of the greatest importance in the theory of atomic and molecular structure. It is difficult to describe its physical nature. All that can be said is that it is the natural outcome of introducing two physical concepts into the mathematical scheme, namely, the principle of the identity of electrons, and the exclusion principle of Pauli. It is sometimes described as the 'exchange' term and the term in the energy expression arising from it as the '*exchange*' *energy*.

The 'exchange' energy depends on the spin of the electrons, while the Coulomb energy does not. It is this property of the exchange term which has made it of so much importance in the theory of atoms and molecules. In a two-electron system, as in an excited helium atom, for example, the electrons may have the same or opposite spins, and, owing to the exchange term, the energy of the states with the same spins is lower in every case than the corresponding states with opposite spin. The hydrogen molecule is another two-electron system, and here the energy is lowest when the electrons have opposite spin. This appears to be the case in the interaction of most atoms. For certain interatomic distances the energy is lowest, and, therefore, the cohesion greatest, when the electrons of one atom are 'paired' with those of the other atom. The energy of two interacting nitrogen atoms is highest when the spins of the three outer electrons of the atoms are all of them the same, and lowest when the three electrons of one atom are paired with those of the other. This latter condition corresponds to the normal nitrogen molecule, held together—as the chemist describes it—with a triple bond.

The pairing of electrons is thus brought into close

---

[*] From two lectures delivered recently by Prof. J. E. Lennard-Jones, one on "Cohesion", before the Physical Society of London, and the other on the "Quantum Mechanics of Atoms and Molecules", before the London Mathematical Society.

connexion with the valency rules of the chemist, and *chemical homopolar forces* are elucidated to this extent—that they are seen to be a consequence of the same mathematical and physical principles which have been formulated for other branches of physics. This result may conceivably come to be regarded as one of the greatest achievements of the present formulation of quantum mechanics.

The new theory has been successful in explaining other forces, the nature of which was formerly little understood. For a long time it has been known that atoms, which are chemically inert, exert attractions on each other; so much so, that they aggregate together as liquids and solids if the temperature is lowered sufficiently. These attractive forces, usually called *van der Waals forces*, have now in one or two simple cases been calculated deductively from the electronic structure of the atoms. These attractive forces seem to be due not to a static polarisation of the atoms by each other but rather to a rapidly fluctuating mutual polarisation. Atoms are not actually continuous distributions of space charge. They are only to be regarded so on the average. When two atoms are subject to each other's influence, the motion of the electrons in one modifies that of the electrons in the other. They tend on the average to move in phase.

Suppose, for the sake of illustration, that an atom were represented by a linear oscillator, that is by an electron vibrating along a line through the nucleus. Such a system requires only one co-ordinate z to specify it. Then the probability-distribution of the electron in its lowest energy state is a Gaussian error curve ($e^{-\alpha z^2}$), symmetrical about the origin. If two such electronic systems, vibrating along the line joining the nuclei and specified by co-ordinates z_1 and z_2, are allowed to interact, the new probability-distribution is not simply a combination of the two undisturbed probability-distributions of the isolated systems. Calculation shows that as a result of interaction the probability of finding z_1 and z_2 with the same sign has increased, while that of finding them with the opposite sign has decreased. Now dipoles which point in the same direction attract, and those which point in the opposite direction repel. The net result is that the two electronic systems on the average attract. The attractive force for this model and for actual atoms proves to be proportional to the inverse seventh power of the distance.

All atoms and molecules exert on each other an attractive field of this type, but usually this attraction is masked by other larger attractive fields. Only in the case of inert gases or saturated molecules does it become predominatingly important. It is likely that many substances, such as the halogen hydrides, are held together in the solid state by forces of this type. There is a growing recognition, too, of the importance of van der Waals fields in many phenomena at surfaces such as in adsorption.

The problem of *ionic cohesion* largely resolves itself into explaining why some atoms have an affinity for electrons. Such atoms are usually unsymmetrical charge distributions and the nature of the affinity can be understood, though actual calculation of the magnitude is difficult.

Metallic cohesion seems to be due partly to the Coulomb interaction of space charge distributions (the Coulomb attraction referred to above), partly to the 'exchange' phenomenon, and partly to van der Waals attraction. Little is as yet known as to the relative extent to which these various factors contribute to the cohesion of a metal. The general principles seem to be understood. What is now required is a mathematical technique capable of applying them to particular cases.

Selection of Engineering Apprentices.*

How far is it practicable to use psychological tests in the selection of boys for the engineering trade? An attempt to provide an answer to this question has recently been made by the Birmingham Education Committee, under the auspices of which an investigation was conducted by Miss E. P. Allen and Mr. Percival Smith. A report describing the tests used, the methods adopted, and the results obtained has now been published.

Such a report will be of especial value to local education authorities responsible for juvenile employment. Indeed, the Malcolm Committee on Education and Industry has already directed attention to the necessity for this kind of research by authorities upon whom that responsibility rests. The present report deals with one aspect of the wide problem with which such authorities are faced: its authors have also been engaged upon a second experiment, involving still wider issues—the extent to which a series of psychological tests can be of practical use in offering vocational guidance to children when they leave elementary schools.

So far as the engineering trade is concerned, however, one of the first points to be decided was what that all-embracing term meant. In Birmingham, as elsewhere, it covers a multiplicity of occupations, ranging from those followed by practically unskilled manual workers to those needing highly skilled technical experts. For the former, the chief requirement is a varying amount of manual dexterity, and tests of such dexterity would, in their case, probably be sufficient. For those engineering branches which require skilled apprentices, however, the qualities to be sought are a combination of intelligence, mechanical aptitude, ability, and dexterity. With that combination in mind, the report uses throughout the term 'apprentice ability'. Tests were therefore used which would depend *inter alia* on mental processes, but would be definitely associated with mechanical ability.

This primary difficulty of deciding the type of qualities to be sought in connexion with so wide an industry as engineering is, of course, well known to engineers. We stress it here not merely to show its complications, but also as an indication of the care with which the investigators dealt with their problem—a care which will go far towards building up methods and results upon which confidence may fairly be placed.

The groups of individuals selected included third and fourth year apprentices (average age nineteen years) attending part-time courses at the Birmingham Central Technical College; entrants and leavers (fourteen to sixteen years of age) of a school with an engineering bias (Handsworth Junior Day Technical School); of a school with a commercial bias (Aston Commercial School); and of a general secondary school (Yardley Secondary School).

This selection of pupils from differing types of post-primary schools possesses a special interest in view of the present reorganisation of education, which is striving to relate the work of such schools to the needs of industry and commerce. Each has recently tended to make special claims concerning the aims and results of its syllabus. The following summary, taken from Section IV. of the report, would appear, so far as the engineering trades are concerned, to support the claims already made by the junior technical school: "(1) Boys who have had a purely academic training do not improve in ability to tackle these tests to the same extent as boys of a somewhat lower intellectual level who have received further education with an engineering bias. (2) Boys who have had further education with a different vocational bias (commercial) do not improve in ability to tackle these tests to the same extent as boys of a slightly lower intellectual level who have received further education with an engineering bias."

---

* City of Birmingham: Education Committee. Selection of skilled Apprentices for the Engineering Trades. Report of Research. By E. Patricia Allen and Percival Smith. Pp. iv+35. (Birmingham: Education Committee, 1931.)

It is to be noted that the investigators did not use only the method of 'tests'. Criteria of apprentice ability of the individuals were supplied by instructors and the test results were compared with the respective criteria.

Priestley as a Pioneer.

UNDER the title, "Joseph Priestley and his place in the History of Science", Sir Philip Hartog delivered a discourse at the Royal Institution on April 24, a reprint of which, with a postscript dealing with some additional points, has been received. Sir Philip traces the main events in Priestley's life, bringing out the fact that he was more than a man of science; he was a teacher, theologian, politician, and defender of liberal thought. His scientific work has been variously assessed and perhaps some aspects have tended to have been overshadowed by his discovery of oxygen. Priestley made some important experiments in electricity, and his work on the "History of Electricity" includes, among other matters, a statement that the inverse square law is contained in the experimental fact that there is no electrification inside an electrified metal vessel. This was probably the starting point of Cavendish's better known investigations. Priestley also made experiments on electric discharges, which are now seen to have raised fundamental issues.

Priestley's attitude to hypotheses in science is examined, and in his indifference to his own theories and those of others, he is thought to have been influenced by Franklin. In his chemical investigations he accepted the phlogistic theory, as a pupil, with docility, since he was "no professed chemist". His practical investigations of gases, although preceded by important publications of Cavendish, led to the acquisition of much new knowledge on gases. This formed the basis of Lavoisier's theoretical revolution in chemistry. Sir Philip Hartog is inclined to allow Lavoisier more originality in the matter of the discovery of oxygen than has been usual, although he admits in more than one instance that the memoirs of Lavoisier as they finally appeared had been amplified from the original communications, a circumstance which makes it necessary to use the greatest care in dealing with this author. Although Priestley's intelligence "remained intact, bright and lively to the end", Sir Philip thinks his memory was failing him when he wrote his well-known complaint of Lavoisier's claims some years before his (Priestley's) death.

Sir Philip Hartog's discourse makes it clear that Priestley more than once was tempted to adopt Lavoisier's new view of the chemistry of combustion, but that he was restrained by the results of experiments, these being either faulty in themselves or wrongly interpreted. He nearly reached a true conception of the composition of water from his own experiments, but says he "was taught by Mr. Watt to correct this hypothesis", an event which does not help in the attempts which have been made to credit Watt with the discovery of the composition of water. One of Priestley's greatest stumbling-blocks was his confusion of the two inflammable airs, hydrogen and carbon monoxide, which was only cleared up by Cruickshank in 1801. Priestley's work on respiration and that on the growth of plants were the starting points for investigations of others, the first for Lavoisier's great researches on animal respiration.

Sir Philip Hartog believes that it is easy to understand why Priestley's work and his character have been under-estimated in the past. His electrical work and his clear views on the use of hypothesis and on scientific theory generally have been eclipsed by his chemical work, in judging which it is no simple task to divest his language of the enveloping veil of the phlogistic theory. He deserves a greater place in the history of science than he has hitherto been accorded.

Some Phenomena of the Upper Atmosphere.

THERE are three layers in the upper atmosphere in which dissociation is produced by the absorption of solar radiation. These are the layer of ozone, with its maximum concentration at about 50 km., and the two ionised layers at about 100 km. and 220 km. The absorption of solar radiation of any kind in a gas of which the density varies exponentially with height $h(ae^{-h/H})$ has a definite distribution relative to the level of maximum absorption; this distribution depends only on H. It is shown that the main regions of absorption associated with the three layers are well separated, though the dissociation of molecular oxygen which results in the formation of the ozone layer has an important influence on the whole of the overlying atmosphere, in which atomic oxygen is a permanent constituent, its concentration increasing with height. The concentration of ozone, on the other hand, must decrease with height above a certain level, a conclusion which bears on the maintenance of a high temperature in the upper atmosphere.

Milne's theory of photoelectric ionisation is applied to the earth's atmosphere, assuming that the sun's radiation even in the far ultra-violet is that of a black body at 6000°. It suggests that the ionisation of the upper layer is due to the absorption of ultra-violet radiation, probably by atomic oxygen.

Considering both magnetic and radio evidence, it is inferred that the agent responsible for ionising the lower layer consists of neutral atoms from the sun, emitted from the sun at the same time as the charged atoms that are responsible for magnetic disturbance, the number of the two kinds of particles varying in unison, from time to time. They travel together from the sun until within a few earth-radii distance from the earth, when the charged particles are deflected by the earth's magnetic field towards the polar regions, there producing auroræ, while the neutral atoms travel straight on and ionise the sunlit hemisphere.

On considering the origin of the green light of the night sky, making use of Rayleigh's recent measurement of the absolute photometric intensity of the light, it is inferred that the excited atoms that emit the light are produced continuously during the night, the energy coming from energy of dissociation or ionisation stored up during the day. The level of the emission may be assigned as between 100 km. and 200 km.

---

[1] Abstract of the Bakerian Lecture delivered before the Royal Society on June 25, by Prof. S. Chapman, F.R.S.

Birthdays and Research Centres.

Sept. 14, 1849 (old style), or Sept. 26.—Prof. I. P. PAVLOV, For.Mem.R.S. and Nobel laureate in 1904 for physiology and medicine, director of the Institute of Experimental Medicine, Leningrad.

I am continuing the investigation of the highest nervous activity by the method of conditioned reflexes. This investigation includes in its scope the study of the normal activity, as well as that of different pathological states, which we are provoking intentionally, and the recovery of the normal after them.

Sept. 17, 1859.—Prof. F. D. ADAMS, F.R.S., emeritus professor of geology, dean of the faculty of applied science, and vice-principal of McGill University.

I am at present engaged in a study of the historical development of our knowledge of certain phenomena of physical geology and of our views on the nature and classification of minerals in the time antedating the rise of historical geology at the close of the eighteenth century; also in a study of certain points in connexion with the geological relations and petrography of the Palæozoic intrusions of the Monteregian Hills.

One of the most important pieces of work which could be undertaken at the present time in geology would be a comparative and at the same time comprehensive study of the great developments of the Pre-Cambrian exposed in certain typical areas such as those in North America (the Canadian Shield), Finland and Scandinavia (the Baltic Shield), and in South India and Ceylon, as recently suggested by Dr. Sederholm, of Helsingfors, with the view of advancing, so far as possible, our knowledge of the geological succession as set forth in these ancient records of the beginnings of the history of the earth.

Sept. 17, 1870.—Lieut.-Col. S. P. JAMES, F.R.S., I.M.S. (retired), medical officer and adviser on tropical diseases, Ministry of Health.

At the Malariotherapy Centre which was established by the Ministry of Health and the London County Council at Horton in 1925, psychiatric studies on the effect of induced malaria on general paralysis go hand in hand with investigations into the malarial infection itself, its natural history in man and in mosquitoes, its treatment, and its prevention. Recently attention has been devoted chiefly to chemotherapeutic experiments with a view of improving the treatment of obstinate cases of malignant tertian malaria, and to chemoprophylactic experiments having for their object to ascertain whether any known or reputed antimalarial remedy is a true preventive of human malarial infection contracted in the natural way by the bites of mosquitoes. The former experiments have not, as yet, yielded a noteworthy result, but from the latter the striking fact has emerged that the German synthetic preparation ‘ plasmoquine ’, when taken in suitable doses before and after a person is bitten by infective mosquitoes, possesses the remarkable property of preventing him from becoming infected.

These and other experiments now being conducted at Horton indicate that a subject to which attention might usefully be given is the revision of the classical chemotherapeutic method of testing antimalarial drugs (the method devised and practised so diligently by the late Dr. Roehl) in the light of the new knowledge that not all the different phases or forms of the malaria parasite which occur in the human host are amenable to the same drug, and that the problem of controlling malaria by the use of drugs is not so much a problem of finding a drug which is more effective than quinine against the fever-producing forms of the parasite as it is of finding other drugs that will be effective against the sporozoite stage, the sexual stage, and the stage responsible for relapses.

Sept. 18, 1854.—Sir RICHARD GLAZEBROOK, K.C.B., F.R.S., formerly director of the National Physical Laboratory.

The date that stands above, Sept. 18, 1854, will tell my friends that I can no longer ask their interest in or their support for personal investigations. The time for these is over, but in the future there are many problems I would wish them to carry forward to a complete solution.

Thirty years of a not inactive life have been given to the endeavour to bring home to all the need that, if we are to maintain our place in the world, we dare no longer trust to the natural advantages of our position and to the fact that during the past century great Englishmen have been the foremost to advance natural knowledge. We must apply to our daily wants the truths they wrested from Nature.

This lesson was never more necessary than to-day. There are among us men most skilled in unveiling Nature's secrets; others there are well fitted to apply the knowledge so gained to the problems of each day's life. I wish to see the work of these men helped onwards by all means in our power, while at the same time our leaders, and those they lead, grasp the truth that it is on such foundations that they must build.

Sept. 18, 1865.—Sir ALEXANDER HOUSTON, K.B.E., C.V.O., F.R.S., director of water examinations, Metropolitan Water Board.

Systematic search might usefully be made for the presence and numerical abundance of the microbes of epidemic water-borne disease (typhoid and paratyphoid) in sewages, sewage effluents, and in sewage polluted rivers. Very little is known of this subject despite the pioneer work carried out by Wilson, Gray, Begbie, and Gibson, and the Metropolitan Water Board.

The extensive work already achieved in the examination of the dejecta of enteric fever patients and of ‘ carriers ’ should be greatly extended in the direction of estimating the number and not merely the presence of the germs of enteric disease. In positive cases, the opportunity should be seized of determining the vitality of these ‘ uncultivated ’ pathogenic organisms in the materials examined at different temperatures.

Turning next to a totally different problem. Is there not room for further research on the cause, prevention, and treatment of that painful and often most intractable disease herpes zoster, and its alleged relationship with chicken-pox?

Sept. 18, 1881.—Prof. ARTHUR M. TYNDALL, Henry Overton Wills professor of physics, and director of the Wills Physical Laboratory, University of Bristol.

The activities on the experimental side of the Wills Physical Laboratory at Bristol are mainly concentrated upon three subjects: spectroscopy, magnetism and conduction through gases. In each of these branches groups of workers are engaged. My own investigations lie in the last of these, and in the mobility of gaseous ions in particular. We have recently shown that minute traces of impurity may have a profound effect upon the mobility of positive ions. Thus the mobility of positive ions in helium is raised fourfold by the elimination of all impurities. We are therefore engaged upon a re-investigation of the whole subject with improved technique. We also find that the method may be used to analyse the ions present in the various inert gases when contaminated by small amounts of known impurities, and we are thereby obtaining useful information on the phenomena of electron capture and of ionisation by collisions with metastable atoms.

Societies and Academies.

PARIS.

Academy of Sciences, July 15.—The president announced the death of Albert A. Michelson, foreign associate.—**Ch. Fabry**: An interferential level without an air bubble. A liquid, preferably oil, is contained in a vessel the bottom of which is a platinised glass spherical surface of very large radius (500 metres). By means of the interference rings produced, this can be used as a level of high precision.—**C. Camichel** and **P. Dupin**: The various modes of contraction of a liquid stream at the commencement of an efflux.—**Henri Lagatu** and **Louis Maume**: The variation of the physiological relations between the mineral constituents of a plant species.—**M. Ghermanesco**: The *n*-metaharmonic functions.—**René Pallu**: Study of the system H_3PO_4, $Ba(OH)_2$, CO_2, H_2O.—**Agostino Puppo** and **Pietro Longo**: The storm of July 24, 1930, in the Treviso-Udine district. A correction of a misprint in the *Comptes rendus*, June 8, 1930.—**A. Guilliermond**: The mode of formation of the anthocyanic pigments in the flower of *Iris germanica*. The anthocyanic pigments in the flower of *I. germanica* are preceded by the production of oxyflavonols.—**Léon Binet** and **J. Magrou**: Sulphur and growth. The high proportion of glutathione in tissues during the period of proliferation suggested a study of the influence exerted on growth by various sulphur compounds. The activating action of sodium hyposulphite on growth has been demonstrated in the case of cress and of the tadpole.—**C. Levaditi**, **J. Bardet**, **A. Tchakirian**, and **A. Vaisman**: The distribution of gallium in the organism. From the point of view of its distribution in the blood and tissues (rabbits) gallium behaves like bismuth, tellurium, and mercury.—**Bordier**: The remarkable action of diathermic d'Arsonvalisation at a distance.

July 20.—**G. Ferrié**: *Compte rendu* of the general meeting of the International Radio-Scientific Union held at Copenhagen on May 27–June 6, 1931. Details of the various committees and the work allotted to each. —**L. Blaringhem**: A mutation of the common wallflower (*Cheiranthus Cheiri*).—**Gabriel Bertrand** and **P. Serbescu**: The toxic power of aluminium compared with that of iron, nickel, and other metals. Aluminium and iron possess about the same toxic power, both much less than that of nickel and copper. There is no definite proof that small repeated doses of aluminium are toxic.—**M. de Broglie** and **L. Leprince-Ringuet**: The artificial disintegration of aluminium.—**C. Sauvageau**: The rôle of Aglaozonia of parthenogenetic origin.—**H. Milloux**: Certain integral functions and their derivatives.—**Lucien Féraud**: Arithmetical study of the permanent stability in the neighbourhood of an equilibrium point.—**Alfred Rosenblatt**: The movements of viscous liquids symmetrical with respect to an axis.—**Pierre Dive**: An exclusive property of ellipsoidal homoids.—**G. Fayet**: The orbits of the planets Neptune and Pluto.—**Auguste Claude**: The use of geometric loci for the representation of observations of passage in the meridional telescope.—**L. Bouchet**: The electromotive forces of two liquid batteries and their variations with the dilution of the solutions.—**F. Holweck** and **P. Chevallier**: A 150-kilowatt triode capable of being taken apart.—**Horia Hulubei**: A system of bands of mercury in the neighbourhood of its resonance ray.—**J. Cabannes** and **Mlle. D. Osborne**: The depolarisation of lines of the CO_3 ion in the spectrum of the light diffused by a calcite crystal.—**Jean Becquerel** and **Louis Matout**: The decomposition of the absorption bands of xenotime by a transverse magnetic field. The conditions of symmetry in relation with the crystalline symmetry. A new interpretation of the magneto-electric effect.—**Constantin Salceanu**: The invariant of magnetic rotation of some organic substances in the fused state. —**Mlle. Quintin**: The hydrolysis of copper sulphate. —**René Audubert**: The rôle of water in photovoltaic cells. The experiments detailed establish that water plays an essential part in photovoltaic phenomena, its influence being mainly exercised in the adsorption layer at the surface of the electrode.—**Tcheng Datchang**: The purification of the protactinium fixed on tantalum oxide, with reference to the estimation of protactinium in radioactive minerals. In determining the proportions of protactinium present in radioactive minerals, it is essential that radium, ionium, and polonium should first be removed. Details of satisfactory methods of separation of these three elements are given.—**Albert Portevin** and **Pierre Chevenard**: The graphitisation of steels at a low temperature.—**P. Laffitte** and **M. Patry**: The deflagration and detonation of mercury fulminate.—**Georges Lévy**: α-Ethylnaphthalene and its hydrogenation products.—**A. Mailhe** and **Creusot**: The transformation of toluene and of xylene into methane. A quantitative study of the hydrogenation of these two hydrocarbons in the presence of reduced nickel as catalyst at varying temperatures.—**Émile André** and **Charles Vernier**: The rotatory power of ricinolamide.—**F. Dupré la Tour**: The polymorphism of malonic, succinic, and glutaric acids as a function of the temperature. Each of these acids exists in two forms, with a definite transition temperature.—**Louis Glangeaud**: The structure of the primary massif of Algiers.—**J. Malavay**: The geology of Mauritania of the Nord.—**Y. Milon** and **M. Sire**: The interdependence of the Tertiary and Quaternary formations in the Vilaine and Mayenne valleys.—**Ch. Poisson**: Phenomena due to the meeting of a monsoon and a trade wind on the southern Indian Ocean.—**H. J. Maresquelle**: The action of *Bacterium tumefaciens* on regeneration, in the root of *Taraxacum dens leonis*.—**Pierre Gavaudan** and **Robert Cazalas**: New observations on the spermatogenesis of the Characeæ. The nature of the granulated band and the appearance of carotene and of chlorophyll in certain spermatocytes. —**Charles Pérez**: Organogenesis of the substitution buds in *Chlorogaster*, parasite of the hermit crab.—**A. Policard**: Histochemical researches on the initial lesions of experimental pulmonary silicosis (silica plaques).—**Aloncle**: The synergism of hypophysine and thymine.—**A. Leulier**, **B. Pommé**, and **R. Delaye**: The distribution of potassium in healthy or pathological muscle.—**E. Roubaud**: Cyclic evolutive fatigue and tireless strains in the common green fly *Lucilia seratica*.—**E. Chatton** and **Mme. M. Chatton**: The conjugation of *Paramœcium caudatum* determined experimentally by modification of the associated bacterial flora.—**Mlle. D. van Stolk, J. Guilbert,** and **H. Pénau**: Carotene and vitamin A. The absence of xanthophyll in the carrot has been proved, also the presence of more than one carotene, differing in their physico-chemical properties, but all possessing physiological activity.—**A. Paillot**: The gattine of the silkworm.

Geneva.

Society of Physics and Natural History, May 21.—**M. Decker**: The synthesis of Bichler and Napieralski. The author recapitulates the history of a very important synthesis in the field of the alkaloids. It had its origin in a work of Bichler, published in 1893, and appears again in the works of Pictet and of Decker in 1909; it served as the starting-point of the work of Robinson in England in 1915, and was presented as a novelty in 1930 by Spāth of Vienna.—**Jean Deshusses** and **Louis Deshusses**: Some insects specially injurious to cultivation in French Switzerland. The laboratory of agricultural chemistry (Châtelaine-Genève) points out cases of new, or little known, parasitism, the agents of which are Diptera or Lepidoptera. Fifteen insects are described which cause damage to cultivation in Geneva and French Switzerland. The most interesting are: *Ophionya pinguis* and *Phytomyza continua* on chicory, *Argyroploce antiquana* on the Japanese artichoke, *Evetria buoliana* on various pines, *Dioryctria abietella* on the Douglas pine, *Perrisia violæ* on the cultivated violet.

Leningrad.

Academy of Sciences, *Comptes Rendus*, 1931, No. 2.—**G. Nadson** and **G. Filippov**: The formation of new stable races of micro-organisms under the influence of X-rays. (3) Formation of races in *Sporobolomyces*. The authors describe the regularities in the process of the dissociation of cultures of *Sporobolomyces* with the formation of new races described in a previous paper. The action of X-rays may produce organisms more complex than the original. For example, *Sporobolomyces* may be obtained from *Torula*, or from *Cryptococcus*. Forms with atavistic characters can also be obtained.—**G. Nadson** and **E. A. Stern**: The action of the ultra-violet and X-rays on the yeast cell. Both kinds of rays produce similar changes in the yeast cells, but the action of ultra-violet rays is more rapid than that of X-rays. The exposure results at first in an excitation, then in a depression, degeneration, and death. The rays act on the cell itself, not through the changes in the medium.—**W. Tranzschel**: An æcidium of *Puccinia pygmæa* Erikss. on *Berberis*. *Puccinia pygmæa* parasitic on *Calamagrostis* proved to be able to produce æcidia on *Berberis*. Differences of these æcidia from those of *P. graminis* are described. It is probable that *P. baryi* and *P. gibberosa* also produce æcidia on *Berberis*.—**G. Vereschagin**: The influence of Lake Baikal on the summer thermic régime of the river Angara. Determination of the temperatures of water in Lake Baikal and the river Angara flowing from it.—**N. S. Smirnov**: Two new species of Rotatoria from the Ussuri region. Descriptions of *Lepadella rezvoji* sp. n., and *Testudinella tridentata* sp. n.—**S. Tchernov**: The identity of *Gymnodactylus microlepis* Lantz and *G. fedtschenkoi* Strauch. Differences between the two species do not exceed the limits of individual variability in *G. fedtschenkoi*.

Melbourne.

Royal Society of Victoria, June 11.—**Charles Oke**: The Aculagnathidæ, a new family of Coleoptera.—**W. J. Harris** and **R. A. Keble**: Victorian graptolite zones, with correlations and descriptions of new species. Gives history in research in Victorian graptolithology, details of twenty zonal associations and tabulation, and an attempted correlation of zones with those of the northern hemisphere. Photographic illustrations of zonal species and descriptions of new species of zonal and subzonal importance include the following: *Diplograptus austrodentatus*, *Phyllograptus nobilis*, *Goniograptus palmatus*, *Brachiograptus etaformis*, gen. et sp.nov., *Didymograptus forcipiformis* Rued, and *D. dependulus*.—**A. B. Edwards**: The geology and petrology of the Black Spur area (Healesville). A series of acid igneous lavas (rhyolite and dacite) are mapped and described in this area. The lavas are intrusive into Silurian sediments and are considered as of Upper Devonian age. They include four varieties of dacite, one of which, a new Victorian type, contains phenocrysts of quartz and hypersthene. The dacites are part of a series associated with rhyolite and granodiorite. An explanation is given of the pyrogenetic reactions by which biotite is formed from hypersthene and also from ilmenite.

Sydney.

Royal Society of New South Wales, July 1.—**C. A. Sussmilch**: The Bathurst Senkungsfeld: The district immediately surrounding the town of Bathurst commonly known as the Bathurst Plains has an undulating surface with a general elevation of about 2400 ft. It is surrounded on all sides by higher tablelands. The change in elevation from the Bathurst region to the high tablelands surrounding it is everywhere an abrupt one, the dividing line being a well-marked scarp. It is considered that the scarps are fault scarps, and that the lower Bathurst block is a *Senkungsfeld* or 'sunk-land'. The most striking of these scarps is that separating the Mt. Lambie tableland from the Bathurst area. This consists of two faults with a combined throw of about 1700 ft. It is not considered that this area actually subsided, but that during the uplift which produced the existing tablelands, the Bathurst district lagged behind and was not uplifted as high as the surrounding regions. The Bathurst Senkungsfeld is drained by the Macquarie River, which leaves this lower area at its north-west corner by an almost impassable gorge which traverses the Orange tableland; the differential uplift was sufficiently slow to have enabled the Macquarie River to keep pace in cutting down its channel in the more rapidly uplifted Orange tableland.

Vienna.

Academy of Sciences, July 9.—**E. Beutel** and **A. Kutzelnigg**: The deposition of sulphide films on metals.—**A. Kailin** and **H. C. Hardt**: The velocity of catalysed hydrogenation. Experiments were made with nickel precipitated on kieselgur as catalyst acting on the esters of cinnamic acid.—**A. Zeller**: Resistance experiments on red algæ. Mixtures of salts, isotonic with natural sea-water, but with one or more constituents missing, were used. The seaweeds were first immersed in the mixtures, then brought back into complete sea-water and the damage compared.—**K. Brunner**: New derivatives of 3·3-dimethylindolin.—**H. Schober**: The spectrum of rhenium. The arc spectrum in the visible region between λ5400 and λ8000.—**K. Graff**: The clearness of the winter sky during twilight on the island of Mallorca. **K. Graff**: Visual measurements of planetary colours. Various colours were met with from *B*7 (pure white) to *K*8 (red). Mars was one colour class redder, Uranus two classes bluer.—**E. Dittler** and **O. Kuhn**: The genesis of bauxite in the Upper Sann valley. Bauxite is the last residue on solution of andesite.—Eleven separate communications follow from the Experimental Biological Institute; director, H. Przibram. These concern the regeneration of limb-bones after operation on newts, and the regeneration of feet and antennæ after operation on locusts, etc.—(165). **L. Chen**: Regeneration of long bones after removal of one-third from within the limbs of the newt *Triton cristatus*.—(166) **L. Chen**: Regeneration after implanting of sixths of the femur of the salamander *S. maculosa* in the upper thigh of the newt *T. cristatus*.—(167) **J. Gebauer**: Autoplastic replacement of long bones in the limbs of *T. cristatus*.—(168) **H. Przibram**: Antenna and leg regeneration in the locust *E. herculeana*.—(169): Antenna and leg regeneration in the walking leaf insect *Phyllium siccifolium*.—(170): Antenna and leg regeneration in the European locust *Bacillus rossii*.—(171): Antenna and leg regeneration in the locust *Diapheromera femorata*.—(172): Antenna and leg regeneration in the locust *Dixippus morosus*.—(173) **H. Przibram and F. Friza**: Antenna and leg regeneration. Comparative inquiry on the position and rôle of Johnston's organ.—(174) **P. M. Suster**: Leg regeneration after extirpation of the ganglion in *Sphodromantis bioculata*.—(175) **P. M. Suster**: Antenna regeneration after extirpation of ganglion in *Sphodromantis bioculata*.—**P. Krüger and F. Furlinger**: Histology and chemistry of tetanus and tonus substratum. It is suspected that the chemical metabolism of striated and smooth muscles may be different. Experiments have been made with frogs and analyses made of the phosphate and glucose contents of the different muscles.—**F. Duspiva**: The physiology of the melanophores of fish embryos.—**E. Schally**: The observation of streaks in chemical studies. (4) *D*-streaks and allied phenomena. When various liquids of like refractive indexes are mixed, transitory double-shaded streaks appear, depending in some cases on different velocities of diffusion.—**F. Hölzl and W. Stockmair**: The mobility of some iron-containing ions. Experiments on conductivity of nitro-prussides.—**F. Palm**: Geometrical research on graphical tables for the solution of complete cubic equations.—**K. Strubecker**: Cubic relations among non-Euclidean screws.—**G. Stetter and R. Premm**: Radium Institute Communication (279). Attempts to register α-ray spectra of very weak intensity.—(280) **R. Premm**: Mass spectrum of the positive rays of thorium C.—(281) **F. Hecht**: Criticism of age determination by the lead method.—(282) **P. Krafft**: Absorption spectra of the *M*-series for the elements bismuth, lead, thallium, and gold.—(283) **M. Blau and E. Kara-Michailova**: The penetrating radiation of polonium.—(284) **M. Blau**: The fading of the latent image on exposure to α-particles.—**H. Burchardt**: Regulation of the secretory activity of the seminal vesicle. Experiments on guinea-pigs and rats. The epithelial cells of the mucous membrane vary in height and width. Under pressure of undischarged semen they return to the resting stage.

Nationalism and Science in China.

After spending half a million dollars over a period of ten years and the dispatch of five scientific expeditions to the Gobi Desert, the Central Asiatic Expedition of the American Museum of Natural History, of which Dr. Roy Chapman Andrews is the leader, has been refused permission to continue its work in Mongolia by the Chinese authorities. This refusal comes at a moment peculiarly inopportune in the interests of science. The expedition was about to open up a new field of exploration, which would have been of the greatest palæontological and, possibly, of anthropological interest.

Up to 1928 this American expedition had been in most friendly and cordial relation with the Chinese authorities, scientific organisations and individual investigators. Indeed, for some considerable time a proposal to establish a branch of the American Museum at Peking had been under consideration, and one of the palace buildings had even been selected for the purpose by Dr. Kungpa King, director of the Peiping Museum of Art. But in 1928 these friendly relations came to an end, largely owing to the activities of the Chinese Cultural Society, now the Commission, for the Preservation of Antiquities. The entire collection of fossils and other specimens made by the expedition in 1928 was seized by the Commission and released only after prolonged and tedious negotiation. Permission to revisit Mongolia in 1929 was refused, and resumption of work was allowed in 1930 only on the understanding that the work of the expedition would then be brought to a close. Results obtained in that year, however, seemed to justify reconsideration. Entirely new fossil fields of Pliocene age were discovered east of the Kalgan-Urga Trail. In consequence, application was made for a renewal of the permit in order to follow up this new and important discovery in 1931 and 1932.

In a letter under date June 5 last, the Commission for the Preservation of Antiquities has informed the authorities of the American Museum of Natural History that there is no longer any necessity for permitting members of the Museum to make further trips to carry on the work in Mongolia. It adds, however, that in the future every facility will be accorded American scholars to visit Peking for the purpose of examining geological material from Mongolia "to conform with the principles of non-discrimination between nationalities in respect of science". The grounds for the statement that the necessity for the permit hitherto granted no longer exists, are given in the course of this communication. In addition to the fact that the American expedition has repeatedly declared its intention of winding up its work in Mongolia and discontinuing its trips to that area, the Chinese Government, it is stated, has now organised a Western Frontier Scientific Expedition to proceed to Mongolia, Kansu and Sinkiang " to carry on various scientific researches".

There is a subtle irony in the phrasing " principles of non-discrimination between nationalities in respect of science " which will be appreciated. The achievement of the Chinese authorities in the direction of the attainment of this object merits recapitulation. Action similar to that against the American expedition has been taken against the Swedish expedition in Chinese Turkestan under Dr. Sven Hedin; against the French Trans-Asiatic expedition of Dr. Georges Hardt and P. Teilhard de Chardin; and Sir Aurel Stein, as has been recorded recently in these columns (see NATURE, July 25, p. 144), has been forced to abandon his expedition in Chinese Turkestan after repeated vexatious delays and difficulties raised upon pretexts entirely without foundation. It is sufficiently clear that the Chinese authorities are sincere in the expression of their desire to show no discrimination between nationalities. They propose to exclude them all!

Vigorous, if misleading, not to say untruthful, propaganda by the Commission in the Chinese press has secured popular support for this hostility to foreign expeditions of scientific exploration. It must not, therefore, be concluded that the interest of the Chinese people in drawing a ring-fence around the field of research within their territory, or in the preservation of their antiquities, is greater than it would be in a western population. The agitation has gone beyond the indictment that these scientific expeditions are taking priceless material out of China; it has not hesitated to inflame popular opinion by imputing political motives to them, and accuses their leaders, Sir Aurel Stein, for example, of subversive speeches against the Chinese Government.

A brief survey of the present situation, which Prof. H. Fairfield Osborn, president of the American Museum of Natural History, contributes to *Science* of August 7, gives the text of the letter received from the Commission for the Preservation of Antiquities, and includes in addition a communication by Dr. Roy Chapman Andrews, in which he sets forth the scope, methods and achievements of the expedition in geology, palæontology and archæology since its inception in 1920. It is a remarkable record, and although already sufficiently well known, it was well worth recapitulation in this context. Between the years 1922 and 1930, it has discovered and developed one of the world's great fossil fields with no less than twelve distinct fauna—Lower Cretaceous to Pleistocene. In addition to the dinosaur's eggs, which attained what was, perhaps, in the circumstances, an unenviable notoriety, and the remarkable series of skulls of the animals which laid the eggs, cretaceous mammal skulls and associated parts of skeletons were found which are the only mesozoic skulls known, with the exception of *Tritylodon* from South Africa. It is unnecessary to pursue further this list which, on one hand, is an almost unique record in the sum total of data new to palæontological science, and, on the other, is a monument to the scientific knowledge, organising ability and powers of endurance of those who were responsible for and took part in the expedition. But what will weigh even more with those interested in the branches of research with which the expedition is concerned, when they reflect on the consequences of this premature ending of its activities, is that it is in this field, if anywhere, that we are, perhaps, most justified in looking for further evidence bearing on the descent and earliest history of man—the main objective of the expedition when it was initiated eleven years ago. No Chinese expedition, however expertly manned and however well-equipped when it takes the field, will compensate for the loss of the experience gained in those five journeys of the American scientific workers to Mongolia.

The claims for consideration of the Central Asiatic Expedition on the ground of achievement are strong. But are they stronger than those of Sir Aurel Stein, Sven Hedin, P. Teilhard de Chardin and others to whom in future China will be closed as a field of exploration? Like the American expedition they have co-operated, or have offered to co-operate, with Chinese scientific organisations and individuals, each in their special field. China has gained, not lost, by the work of these great explorers. By their additions to the sum of human knowledge, she has transcended the bounds of nationality and has entered into the universal realm of science. While men of science of all countries have been looking to China for evidence bearing upon problems of world-wide import, her own horizons have been broadened and her students trained. In other circumstances the organisation of a Chinese expedition to Mongolia might have been welcomed as a valuable and progressive measure in the interests of scientific research without any thought as to whether it was an encroachment on a field in which America had secured a right.

Notwithstanding the difficulties of the present political situation, China has won, and continues to hold the sympathies of influential elements in the western world for her desire to assimilate what is most suited to her needs in western culture, and to join in the movement for the advancement of science. Is she by her own action to be placed, as Prof. Osborn has phrased it, in "the column of backward, reactionary and non-progressive nations"?

The Schneider Trophy Contest.

THE eleventh contest for this trophy for marine aircraft was arranged to take place on Sept. 12 at 12.30 P.M., over a triangular course above the Solent and Spithead off the Isle of Wight. Owing to the last-minute withdrawal of the French and Italian challengers, the event resolved itself into a mere flight around the 350 kilometres (217·5 land miles) course by one of the British entrants in order to qualify. The flight was completed on Sept. 13 by Flight-Lieut. Boothman, R.A.F., flying a Supermarine S6B. seaplane, fitted with a Rolls-Royce R engine, at an average speed of 340·08 miles per hour. During the flight he also broke the world's speed record over a measured distance of 100 km. with flying start, at 342·9 m.p.h. The trophy, having now been won by Great Britain on three consecutive occasions, becomes our property, and the Schneider Trophy competition thus ceases to exist.

It has been felt in many quarters that it would have been an act of sportsmanship on our part to have postponed the competition until such time as the French and Italian competitors were ready to race, but it must be remembered that there is much more in this event than the actual race. It is really a competition amongst designers to produce machines capable of flying at speeds greater than those already attained, and engines able to give the necessary power for a sufficient time to complete the distance. The actual flying of the race, with its demand upon the courage, skill, and physical endurance of the pilots, is really only the grand culmination of the whole scheme. The French and Italians were, presumably, confident of being able to do this when they took the initiative in challenging Great Britain. It is known that they have built machines and trained teams to manipulate them, so that their withdrawal at the last moment can only be construed as an admission that the performance of their products falls so far behind what they suspected of ours that actual participation in the race was merely a waste of effort.

It is also becoming increasingly evident that the regulations governing this competition, which were intended, when laid down, to promote a general advance in the design of a useful sea-going aircraft, are no longer adequate to guard against the competition being won by a freak machine of very little use except for that specific purpose. The closing of this chapter in seaplane development will consequently make an opportunity for some public-spirited person or body to offer a fresh trophy under rules more suited to modern requirements. Newspaper reports have already hinted at the name of M. Schneider's successor.

The figures of the speeds of the winners of the succeeding races give an interesting clue to the phases of development through which the design of aircraft and engines has passed since the inception of this competition:

Year.	Machine.	Country.	Average Speed (m p.h.)
1913 . .	Deperdussin	France	45·75
1914 . .	Sopwith	Gt. Britain	86·75
1920 . .	Savoia	Italy	107·12
1921 . .	Macchi	,,	110·84
1922 . .	Supermarine	Gt. Britain	145·62
1923 . .	Curtiss	U.S.A.	177·38
1925 . .	,,	,,	232·57
1926 . .	Macchi	Italy	246·49
1927 . .	Supermarine	Gt. Britain	281·65
1929 . .	,,	,,	328 63
1931 . .	,,	,,	340·08

The speed of 45·75 m.p.h. in 1913 is misleading, as the pilot did not cross the finishing line correctly, and had to complete another lap. His real flying speed was in the neighbourhood of 70 m.p.h. Thus from 1913 to 1914 there was a small improvement, consequent partially upon improvement in design, but more upon experience in handling machines under racing conditions. The period 1914–20 does not show any great improvement in proportion to the time that elapsed, but it must be remembered that the seaplane was relatively neglected during the War period, the energies of combatants being directed to the improvement of land machines, operating under much different conditions. The step 1920–21 marks a distinct improvement in aerodynamic design of the seaplane, which, although only 3·72 m.p.h. faster, carried only a 200 h.p. engine, as compared with the 550 h.p. of its predecessor. In 1922 the Supermarine flying boat increased the speed considerably, but with a large increase of power, having a 450 h.p. engine. The 1923 Curtiss seaplane marked a decided change in the aerodynamical outlook. It was the first of the post-War competitions in which a seaplane had been used in preference to a flying boat. Previous opinion had held that while a seaplane could be built with finer lines and less head resistance, it could not be made seaworthy enough. Later experience has proved this to be wrong, and all winners since 1923 have been seaplanes. This machine also showed a decided attempt to deal with the problem of reducing the head resistance of the exterior non-lifting parts, such as the floats, engine radiators, etc. Attention to these details resulted in an increase of speed from 145·62 to 177·38 m.p.h. with only 15 h.p. additional.

Having realised the importance of reducing head resistance by good streamlining and limiting frontal area to the minimum possible, the competition then resolved itself into a battle of the engine designers to give more power from an engine without unduly increasing, primarily the frontal area, and secondarily the weight, either of itself, its accessories, or its fuel and oil. Their success can be judged by the fact that in the next five competitions, 1925–31, the horse-powers were 600, 800, 875, 1900, and well over 2000 respectively. In the case of the last two competitions there was actually not only a decrease in frontal area of the engine, but also its shape was modified to conform to the requirements of good streamlining of the nose of the machine in which it was installed.

At the same time, improvements in the actual aircraft have been continuous, although not so radical. The dispersing of the excess heat from the engine-cooling water has been one of the principal problems, and on the 1931 machine practically the whole of the wings, the tops of the floats, and the sides of the body are covered with a thin annular shell through which the engine-cooling liquid passes, giving a maximum surface exposed to the air without any extra head resistance. The cooling of the engine oil is carried out in a similar manner. A further problem to be surmounted this year arose from the fact that the take-off, climbing, alighting, and taxying test have been arranged so that they are preliminary to, and continuous with, the actual speed flight, instead of being carried out separately as in previous years. This means that more petrol has to be allowed for, which affects both the size of the tanks and that of the stronger structural members necessary to carry the extra weight.

It should be useful now to examine critically what has been attained as the result of the eighteen years' development of this type of marine craft, and to endeavour to profit by these conclusions in framing rules for a new competition. It is quite certain that such machines as are being used to-day are useless in themselves for any other purpose. There are certainly advantages in the fact that national prestige and that of individual firms is increased, and doubtless many engineering lessons have been learned in the course of these experiments that will help to improve the breed of British aircraft, but M. Jacques Schneider's original idea of developing useful sea-going aircraft has been almost entirely submerged in the mere race for speed.

Flying at 400 m.p.h. in the present form of aircraft is much too unsafe to be used as an ordinary means of transport. Such machines are uncontrollable at all speeds lower than about 100 m.p.h., which makes it impossible even to fly them, let alone land or get off in crowded places, or on any but relatively smooth water. Also, the accelerations when turning at these speeds would certainly be distressing, and possibly dangerous, to passengers not physically trained to them. High maximum speed is certainly desirable in order that air travel may exploit it as the advantage that it has over all other means of transport, but it must be accompanied by a more elastic speed range, giving lower minimum speeds and slower accelerations within that range. Another matter in the exploitation of speed is that in order to save time a machine should fly in a straight line from point to point. A really useful seaplane should, therefore, be amphibian in its alighting and getting-off methods, at least for emergency landings.

The question of carrying a useful load has also been entirely lost to sight. The present-day type has practically developed into an engine with wings fitted to it, the body being cut down to the very minimum required to accommodate the unfortunate but necessary pilot. Even if the machine is capable of lifting any surplus load, it certainly has no accommodation for it, because of the desire to keep down frontal area and its accompanying head resistance. It is significant to compare such machines with modern passenger-carrying flying boats, which in spite of the fact that they have been just as keenly developed, by sometimes the same designers, have not progressed far beyond 100 m.p.h. yet in average cruising speeds.

Lastly, there is the question of robustness and its inevitable accompaniment—useful life. No one who has seen and handled, and admittedly been compelled to admire, a modern racing seaplane can contemplate its being used under the rough and tumble of everyday traffic. The working life of the engine on such machines is probably no more than a few hours, even in the hands of the most highly skilled mechanics that the engine-maker can train.

The conclusion that one is inevitably led to is that if such contests of the future are to be national in character, as they have tended to be recently, the energies of the participants should be directed towards producing machines of some use to the world in general. The race for mere speed and record beating is always desirable because of the moral stimulus resulting from any form of competition, but it should be left to the wealthy amateur or commercial enterprise that has direct interests in it, as is done in most other walks of life.

A Plea for Prejudice.

The Place of Prejudice in Modern Civilization (Prejudice and Politics): being the Substance of a Rectorial Address to the Students of Aberdeen University. By Sir Arthur Keith. Pp. 54. (London: Williams and Norgate, Ltd., 1931.) 2*s.* 6*d.* net.

THE gist of Sir Arthur Keith's rectorial address at Aberdeen is expressed in its concluding sentence: "Under the control of reason, prejudice has to be given a place in the regulation of human affairs". If we understand what the distinguished author means by 'prejudice', his thesis is so reasonable that we must begin by lifting our hands to heaven for the publication of the address in its entirety. For by the perusal of isolated extracts we had been regretfully led, like many others, to dissociate ourselves in private thought and conversation from the rector's position, whereas after reading the whole we wish we had given the address ourselves—it is so well put. Moreover, in its insistence on the value of feeling, the address is a useful counteractive to the partiality or abstractness of science.

Perhaps the most delightful thing is that this plea for prejudice should come from Keith, whom we, being backsliders, have always regarded with admiration as one of the staunchest champions of reason. Drive out Nature with the fork of logic, and she is sure to come home to roost. Thus Keith, of all men, pleads for prejudice!

Everything depends, however, on what the word is taken to mean, and the author leaves us in no dubiety. How charmingly he puts it: "In the parliament of human nature, as in that of our national affairs, there are two houses—an upper, the 'head'; a lower, the 'heart'. . . . The legislators who serve in the lower house or heart are our feelings and passions, our hopes and fears, our likes and dislikes [at home, by the way, in the lower or basal centres of the brain]. . . . The progress of civilization has been possible just because man has been able to bring his lower house or heart more and more under the control of his upper house or head," that is to say, his reason, his logical faculty, his power of conceptual inference or of experimenting with general ideas (which is at home in the cerebral cortex, as who should say). We understand, then, that our prejudices are our inborn likes and dislikes, and the rector's thesis is that they must be given an assigned place in our thought and action.

Among 'prejudices' Sir Arthur Keith includes our loyalty to our Alma Mater and our love for our mother, our national and local patriotism, our pride of race, and so much more that the word becomes synonymous with our deeply enregistered inborn feelings. Whether we call them, with Thomas Reid, "original and natural judgments", or regard them with modern psychologists as part of the primary unconscious, matters little. There they are, activating and motivating us, colouring our thought and action, undeniable realities. "They turn favoured opinions into facts. A fact to the faithful is a prejudice to the sceptic. . . . Prejudices and sentiment are first cousins." Just as Carlyle, speaking of man, said "Prejudice, which he pretends to hate, is his absolute law-giver", so Keith in his enthusiasm for prejudice declares, with all his anthropological learning behind him, that "man has become what he is, not by virtue of his head, but because of his heart". Inevitably one shakes one's head, for who shall escape his prejudices in favour of that member?

This brings us to the second part of the rector's argument. Prejudices form a powerful part of our inheritance, grafted into us because they have been of survival value, or, in the author's teleological language, because of their "evolutionary purpose". "Nature has organised the lower house of man's heart to serve her ulterior object—the production of higher and better races of mankind." This almost verges on the theological—not that we think the worse of it for that!

But however we phrase it, part of Nature's tactics or part of the process of human evolution was the segregation of new varieties or sub-species into distinct tribes (possibly hormonic in origin), and in addition to selection there has operated the factor of isolation—a term applied to all the ways of narrowing the range of intercrossing. Seas and rivers, mountains and deserts, and the like, were useful in this isolating, but Nature "established her real and most effective barriers in the human heart". Automatically those tribes survived that had the strongest prejudices in favour of keeping themselves to themselves in their marriages, the strongest antagonisms to other tribes—the ‘ race-prejudices ’ of to-day ; and not less powerful than these was that “ strange bubble of the human blood —the inbred love of independence ”. “ Nature made sure of her tribal teams by making this love of independence a dominant passion ”, whence the world-wide success of the Scot.

So far the rector’s argument seems unassailable, except that, for more or less legitimate rhetorical (in the true sense) purposes, he uses the term ‘ prejudices ’ in a very wide way. We are full of ancient prejudices, which have powerful hands and feet, and some of them were of survival value in the establishment of tribes in prehistoric times, “ standing to our historic period as a year does to a day ”.

Now, however, comes the crux of the argument : Prejudices were once of racial value, but is it not time that we subjected them to criticism and sifting, repression or sublimation ? No doubt, the deep inborn feelings are still in some measure part of our heritage—“ a tribesman’s heart, with its loves and hates, its likes and dislikes, its heritage of prejudices, still beats in every human breast”. But is our primary unconscious exempt from evolution? Does our ‘ tribesman’s heart ’ live a charmed life in the arcana of the changeful germ-plasm ? Are we not always summoning our primeval prejudices before the tribunals of reason and of socially-acquired sentiments ? May we not safely relegate a good many of them to a rationalised shelf in that museum of relics which willy-nilly we carry about with us, embodied or enminded ?

Now, Sir Arthur Keith’s convinced answer is that we should hold by our prejudices. “ Race prejudice, I believe, works for the ultimate good of mankind and must be given a recognised place in all our efforts to obtain natural justice for the world.” The ideal of all mankind sleeping peacefully under one tribal blanket is, he says, Utopian ; and even if it were possible, it would cost too much in the involved miscegenation. The price of universal peace is the loss of our racial birthright. On the other hand, the price of racialism is said to be the continuation of “ Nature’s old scheme of intertribal rivalries and eternal competition ”. So the two prices have to be weighed against one another. In spite of Sir Arthur Keith’s heart (‘ the future of my dreams is a warless world ’), his head wrings from him the conclusion that “ Nature keeps her human orchard healthy by pruning ; war is her pruning-hook. We cannot dispense with her services”. But there is a wide difference between Nature’s discriminate sifting (natural selection) and the very indiscriminate and dysgenic thinning which man illustrates in modern warfare. It is a woeful confession of human ineptitude if we cannot find for natural selection, which civilization insists on rejecting, any better substitute than modern war. The rector says that if we accept Nature at all, we have to accept her altogether. But this is just what we do not do. To use his attractive teleological language, one of Nature’s ends is just to make man discontented with following her, and it is that ‘ divine discontent ’ which man expresses in every effort to raise the struggle for existence into an endeavour after well-being.

In an admirable way, Sir Arthur Keith weighs racialism against deracialisation, self-determination against leagueism, nationalism against mongrelising, using the ‘ head ’ most deftly to give the ‘ heart ’ a hoist up ; and we can find little to object to in his practical conclusion : “ Give our prejudices a place in our civilization, but keep them under the control of reason ”. In other words, we should be impelled by our ‘ head ’ to scrutinise our ‘ heart ’ from time to time, giving some of its prejudices a pat on the back and subjecting others to a Lenten discipline.

We venture to lay emphasis on Sir Arthur Keith’s conclusion, which we might sum up in the words “ pay heed to reasonable prejudices ”, for we must in all these discussions of high affairs avoid the “ this or that ” fallacy. We cannot divest ourselves, for example, of our national prejudice, and there is no reason to try to do so, unless it becomes insular and chauvinistic. At the same time it is becoming increasingly possible to think sympathetically and understandingly of other nations and their interests, and to begin at least to look at all human problems in the light of the growing interdependence of the peoples of the world. We need not think of our country less though we think of the world more. We may preserve and even strengthen our appreciation of what is precious in nationality, and yet become, though not with ease, loyal citizens of the world. We do not agree with the distinguished rector that this culture of our tribal heart would necessarily involve us in any “ pooling of our blood ”.

Similarly, while it is our deepest personal conviction that human progress at this critical time depends upon bringing strict science to bear on all our practical problems, we are not thereby forced to depreciate the worth of certain elements in our primary unconscious or of the higher values which lie for the most part beyond scientific inquiry. Science is not the only right-of-way towards truth.

We cannot leave this thought-compelling address without expressing our admiration of its fine style, as picturesque as it is pithy, as lucid as it is lightsome. It must have been delightful to listen to, especially in a place where the *genius loci* has such a notably hard head. This is said "without prejudice".

An advocate cannot speak on two sides at once, but when a similar occasion arises, as it will, we hope Sir Arthur will take for his subject the pruning of prejudices; for we are sure that he could deal with that supplementary subject with the same convincing illumination that his present plea illustrates. J. A. T.

Short Reviews.

Deserts and the Birth of Civilizations. By A. J. McInerny. Pp. 46. (Paris: Herbert Clarke, 1931.)

MR. MCINERNY attacks an old problem at a new angle. Like others before him, he would see the influence of the desert in the origin and growth of civilisation. He differs from them in making it solely responsible. In fact, the motto of his essay is "No desert, no civilisation"; and he goes so far as to suggest that any attempt to cultivate desert lands by irrigation at the present day would be a mistake and a possible danger. While it is beyond question that the formation of the great Saharan Desert was crucial in the early history of mankind, few archæologists would be prepared to follow the author in attributing the whole subsequent development of civilisation to the action of the desert areas. In Mr. McInerny's view, they have acted as laboratories for the purification of the air and the release of ozone, thus creating an atmosphere propitious to the development of intelligence and the bleaching of the skin—in short, producing the white man.

Mr. McInerny points to the fact that, with certain exceptions, the great civilisations of the past lie to the north of a series of desert belts, and argues from this that it is not to migrations or to temperature that we are to look for the cause of advance in culture, but in the flow of purified air from the desert zones towards the north. The similar flow towards the south, to the negro or dark belt, could only mitigate, but not eradicate, the more unfavourable conditions of the damp atmosphere, laden with organic impurities, of the tropical forested area. Mr. McInerny is not very successful in explaining away the exceptions in the civilisation of the Yangtse valley and that of Central and South America, where the deserts lie to the north; and if migration is eliminated, the air currents of western Europe seem to be a difficulty. In fact, the author tries to prove too much. Had he endeavoured to show that the character of the atmosphere was one of a number of factors in the problem, he would have had a better chance of carrying conviction.

Hunger and Love. By Lionel Britton. Pp. xi + 705. (London and New York: G. P. Putnam's Sons, Ltd., 1931.) 7*s.* 6*d.* net.

LIONEL BRITTON first became known to the reading public as the author of "Brain, a Play of the Whole Earth", sponsored by Bernard Shaw, praised by Hannen Swaffer, and proclaimed a work of genius by St. John Ervine. His new novel has an introduction by Bertrand Russell. One therefore approaches it with high expectations. It is not customary to review novels in this column. After reading the book, the reviewer is not convinced that its contents justify any departure from the usual practice of NATURE. True, there are frequent, almost too frequent, references to protons and protoplasm. These in themselves are not sufficient to justify the claim that the author has written the novel of the machine age. It is a long soliloquy, in which the hazy outline of Arthur Phelps occasionally obtrudes to remind the reader that it is intended to rank as fiction rather than philosophy.

It took Lionel Britton eight years to write the book: the reviewer took six months to read it. Only the prospect of having to write a short notice of its contents sustained him to the end. Britton says a good many penetrating things about contemporary civilisation. The reviewer shares many of his prejudices and most of his opinions, when they are not susceptible of proof. Unfortunately, his way of stating them is prosy, prolix, and disorderly. People who like *Ulysses* may like "Hunger and Love". Scientific workers, who generally attach importance to intellectual tidiness and coherent expression, will be inevitably repelled. Of the few who start it, still fewer will finish its seven hundred and five closely printed pages. It has captured the temper of contemporary biological realism far less successfully than Charlotte Haldane's "Brother to Bert" or the earlier novels of Mr. Wells.

An Introduction to Human Experimental Physiology. By Dr. F. W. Lamb. Pp. xii + 335. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1930.) 12*s.* 6*d.*

THERE can be no question that the best study of man is upon man himself, but the arrangement of organised experiments for class work on this principle presents many difficulties. Dr. Lamb, as the result of ten years' trial, has succeeded in compiling a workable course of about fifteen lessons on each of the three systems—blood, respiration, and circulation.

Not only will this scheme of investigation of normal man serve as a most desirable preparation of medical students for work in the wards, but also the selection and presentation of the experiments prescribed will satisfy the demands of scientific education. In schools where the classical physiology occupies the preliminary years, this book might well form the basis of a course in clinical physiology during the period given to the study of medicine.

Rumford and the Royal Institution: A Retrospect.

By T. E. JAMES.

BENJAMIN THOMPSON, knighted by George III., and created Count von Rumford by the Elector Palatine of Bavaria as a reward for his services, was born at North Woburn, Massachusetts, on March 26, 1753, and he died at Auteuil, near Paris (where he had settled), on Aug. 21, 1814, aged sixty-one years. His career in early youth was a response, as in many other instances in a new colony, to the varied and often lowly occupations near at hand. For a time he was in the medical faculty at Harvard, and he also engaged in schoolmastering. No one could have foretold that he stood on the threshold of events from which emerged, as if preordained, the governing factors of his life. A matrimonial venture at twenty soon ended in convenient separation. There was a child of the union.

FIG. 1.—Count von Rumford, F.R.S. From the painting after Moritz Kellerhoven, in the National Portrait Gallery, London.

Thompson was a major of New Hampshire militia when the American War of Independence broke out, but he became suspect as one showing 'unfriendliness to the cause of liberty'. Removing to Boston (or shall we say escaping ?), he was arraigned there; finally he cleared himself of the charges against him. In 1776 Boston was evacuated and Thompson's selection to carry the news to England confirmed his allegiance to the mother-country. In favour here, he occupied a post in the Colonial Office, becoming afterwards an under-secretary (1780), charged with military duties relating to the British forces. Next, he appeared in service in America as a lieutenant-colonel in George III.'s American Dragoons. Returning to England in 1783 (then thirty years of age), he retired on half pay, with the rank of colonel.

So far, vicissitudes had had triumphant and material issues. Thompson's record as an experimental philosopher begins during these latter periods. It forms a chapter by itself, too diverse for inclusion here. However strange it may seem, he had been familiar with the discoveries and implications of contemporary science. They did not attract him as diversions, but met natural promptings. In 1779 he was elected a fellow of the Royal Society and in 1792 he received the Copley Medal. Later (1799), he was a member of Council of the Society.

In 1784, Sir Benjamin Thompson, newly knighted, entered on a completely novel mode of life. The Elector Charles Theodore of Bavaria pressingly solicited his services at Munich to initiate schemes in mitigation of social and economic disorders in his dominions. Leave of George III. having been obtained, our soldier-philosopher set forth, actually remaining at Munich for ten to eleven years—the keystone of the arch of progress being military persuasion, to use a mild word, in co-operation with civil authority. Suffice that, as an apostle of order, he routed chaos. Meantime his philosophical studies were pursued, coupled with a vast output of political and economic writings. The following unpublished letter (in holograph *) will, perhaps, be of interest, as indicating two kinds of leanings:

MUNICH, 10*th May*, 1797.

Gentlemen, I send you herewith my Seventh Essay,† which I shall be glad to see published as soon as possible. You will send me 12 copies of it (through Mr. James Meyer of Leaden-hall Street) as soon as it is out of the press. You will please to send me at the same time—or rather immediately on the receipt of this letter—a collection of all the Pamphlets that have been published on the subject of Mr. Pitt's Bill for making better provision for the Poor. You will direct Mr. Meyer to order his Correspondent at Flamborough to forward these articles to me *immediately* by the Diligence, addressed to myself at Munich.

I have hitherto been prevented from sending you my Essay on the "Construction of Kitchen fire-places" by an earnest desire to make that Publication as perfect as possible. I have hopes however of being able to forward it to you in a few weeks.

I am, with much Regard and Esteem,
Gentlemen,
Yours most sincerely,
RUMFORD.

Messrs. Cadel, jun^{r}. & Davies,
London.

P.S.—You will please to make presents in my name of the *Seventh* Essay to all those to whom I requested Presents might be made of my *Sixth*.

Before returning from Bavaria it was sought to make Count von Rumford a Minister at the English Court, representing Bavaria. Rejection was emphatic. He was a British-born subject. Thereupon the Count resumed residence in London as a private citizen. The rebuff had unsettling elements; he entertained the idea of a domicile in America, but gave it up, and certainly there were difficulties, for he had incurred legal disabilities. In the end, America saw him no more, although his fame had crossed the ocean, and had received ample recognition.

* Archives, Patent Office Library. By courtesy of the Librarian.

† Essay VII, "Of the Propagation of Heat in Fluids", is prefaced thus: "It is certain that there is nothing more dangerous in philosophical investigations, than to take anything for granted".

It was at this time that Count Rumford published his historic suggestions which ultimately formed the basis upon which the Royal Institution was founded in 1799. Drawn up in pamphlet form extending to 50 pages, this issue was widely circulated in North America and elsewhere.[*] The title ran thus:

"Proposals for forming by Subscription in the Metropolis of the British Empire A Public Institution for diffusing the knowledge and facilitating the general introduction of Useful Mechanical Inventions and Improvements, and for teaching, By courses of Philosophical Lectures and Experiments, The Application of Science to the Common Purposes of Life."

In 1802, Rumford left England for Paris, never revisiting us. To everyone's surprise, he married, in 1805, Mme. Lavoisier, widow of the great chemist, but a separation followed in 1809. His daughter's comment on this venture referred to it as a bold, imprudent step, completing many vexations. By now the strain of military duties had, without doubt, weakened his bodily powers; maybe in some degree his faculties.

Posterity must envisage many blanks and imperfections in any real biographical estimate of this remarkable man. Rumford was more than a dual personality in whose study on that basis the springs of conduct could receive adjustment. A restless youth, followed by moods of militarism, was the ally throughout of a natural philosophical bias. The latter did not, however, tutor the senses, or restrain a riot of philanthropic fancy and effort. Could he have made philosophy the dominating influence, eschewed certain illusions and reaffirmations made in middle life, a calm and dignified passage into that older state which has finality in sight might have been prophesied with some approach to certainty. But it was otherwise.

RUMFORD'S GIFTS FOR SCIENCE.

Allusion may be made at this point to a period in Rumford's life when he made certain endowments for scientific purposes, applicable in England and in America. Writing to Sir Joseph Banks in July 1796, he intimated his desire to establish a prize medal in gold (with silver replica) in recognition of studies in the philosophy of heat or light, the awards to rest with the Royal Society of London. Whether preliminary discussions on the subject had taken place with Banks is not known. But by that time Rumford had been a fellow of the Society for seventeen years. He had bid farewell to Munich, was again visiting London, enjoying its scientific life—as witness, he dined twice at the Royal Society Club in 1796. The terms of this Rumford gift need not be recapitulated; but it may be noted that the original design for the medal (1797) did not bear the effigy of Rumford. This early pattern was abolished in Victorian times and the portrait-head of Rumford adopted in perpetuity for the obverse of the medal.[*] The initial allotment was made to Rumford himself in 1802 and as for the year 1800; he did not receive it until 1804, when it was sent to him at Paris by the hand of the president, Sir Joseph Banks—"the first opportunity I have had, though decreed a year and a half ago", wrote Banks. The American Academy of Arts and Sciences received on the same date as the Royal Society a similar offer, addressed to John Adams, covering 5000 dollars, but restricted to researches made in "any part of the continent of America, or in any of the American Islands". They placed the bust of Rumford, in uniform, on the medal, which the English Society could not, in all the circumstances, have done. The Academy's first award was not made until 1839.

BEGINNINGS OF THE ROYAL INSTITUTION.

It is recorded that on June 29, 1799, at a meeting of the Managers of the new foundation, the Earl of Winchilsea, as president, acquainted them that he had had the honour of mentioning it to His Majesty King George III., who had been graciously pleased to honour it with his patronage, and to allow it to be called the Royal Institution. It was incorporated on Jan. 20, 1800, and arms, crest, and supporters were granted on Jan. 31.

George Finch, ninth Earl of Winchilsea and fifth Earl of Nottingham, who was chosen first president, occupied a position confirmed and retained for fourteen years. Since he was not, in the precise sense, a man of science, we are referred to general considerations, and those of a personal nature, as justification for such marked and extended confidence. Doubtless he was an acceptable colleague in Rumford's view, on the ground of events in the Earl's career, parallel in certain respects with those in his own. Born at St. James's, Westminster, in 1752, and educated at Eton and Christ Church, Oxford, George Finch succeeded to the peerage in 1769. He died in London on Aug. 2, 1826, aged seventy-three years, bearing the contemporary reputation of being "a nobleman of the old school and a high bred gentleman in his manners". Burley-on-the-Hill, Oakham, Rutlandshire, was the family seat and the Earl became, in course of time, lord-lieutenant of the county.

The American War of Independence found Winchilsea a staunch adherent of George III. He made Rutland an intensive recruiting area for an infantry regiment, raised (so the story went) at a cost of £20,000, serving abroad himself as a volunteer, and becoming (1780) lieutenant-colonel of the 87th Foot. When he settled in England, he enjoyed considerable social and political influence. A member of the Board of Agriculture, he was held in high repute as a practical and discerning landowner, most helpful in days of national difficulty. Loudon ("Encyclopædia of Agriculture", ed. 1825 and 1831) states that the cottages which the Earl of Winchilsea had built had a kitchen, parlour, dairy, and two bedrooms over; also there were several with small holdings attached of from 5 to 20 acres. He also encouraged the practice of letting portions of the pasture to labourers. Another custom was that the cottagers took small portions of farmers' fields to use as gardens—an early step towards our modern allotment system. At the time of the Napoleonic threat of invasion he embodied and commanded, in 1803, a volunteer corps. He was invested a Knight of the Garter in 1805.

---

[*] No copy of this pamphlet exists at the Royal Institution. In 1870 it was reprinted for issue in the *Proceedings*, from a copy at Althorp. There is also one in the British Museum. An original and complete copy of the pamphlet may be seen in the Patent Office Library, bound in at the end of an octavo set of Rumford's Essays, London edition.

[*] Ellis, "Life of Rumford" (1873), says that the head of Rumford on the Royal Society's Medal is from a portrait of him painted in Munich which hung in his house at Brompton, and was presented to the Society by his daughter in December 1831. No such portrait was ever given to the Royal Society.

Winchilsea was elected into the fellowship of the Royal Society in 1807, signing the charter book the following year. In 1822, he accompanied George IV. on his Scottish tour. He was unmarried; and we like to think that he may have made the acquaintance of the youth, Faraday, who entered the service of the laboratory (1813) in the year that he vacated the presidential chair that he had so long occupied.

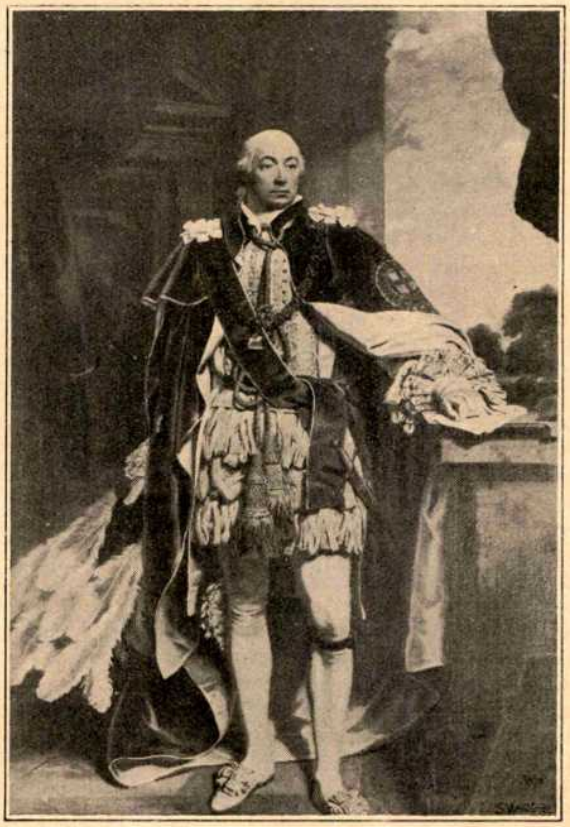

Fig. 2.—The Earl of Winchilsea, K.G., F.R.S., President of the Royal Institution, 1799–1813. Painted by S. Woodforde, R.A., 1808. By courtesy of Miss Jasmine Finch.

Empowered with authority for the introduction of a scheme of philosophical lectures, which, in due course, would be continued in a specially designed theatre, Count Rumford was not long in taking decisions respecting a beginning. In 1799, he made inquiries of Thomas Garnett, M.D., then occupying a professorship in the Andersonian Institution, Glasgow, and very favourably known for his successful experimental presentation of philosophical subjects, for information respecting the plan of courses at that centre.

At the time, these men had never met each other. However, Rumford was sufficiently satisfied with the past and present qualifications of Garnett to make him an offer to transfer to London. Accordingly, Garnett resigned office in October 1799, and was appointed, with managerial approval, the first professor of natural philosophy and chemistry in the Royal Institution. It was certainly the belief of Garnett (a widower) that he and his children would be housed in Albemarle Street *; further, that he would be allowed to practise as a physician. But in these matters Rumford seems to have made arbitrary reservations. Notwithstanding these preliminary drawbacks, Dr. Garnett engaged with the utmost zeal in a series of morning and evening lectures, which proved highly attractive, and at which there were crowded audiences. But an incident of significant import for the professor reveals itself in the terms of a letter from Rumford to Sir Joseph Banks, dated May 29, 1800:

> I am very sorry to find, on making enquiry of Dr. Garnett, that your information was accurate respecting his having ascribed the late discoveries of our friend Volta to the French. . . . I have, however, insisted on its being rectified as far as it is possible, in some future lecture.

This letter was followed the next day by another from Count Rumford, stating that Dr. Garnett proposed to rectify his error, in the subjoined terms:

> Having by mistake, on Wednesday, in the course of my public lecture ascribed to the French philosophers a new and interesting discovery relative to galvanism, which, on enquiry, I find belongs to Professor Volta, of Milan, I feel it to be my duty to state this fact in a public manner, in order that Professor Volta may not be deprived in any degree of the honour of a discovery which so justly belongs to him alone. The first news of this discovery, which arrived in this country in the beginning of last month, was communicated to the president of the Royal Society. . . .

In all likelihood, Dr. Garnett would have set the matter in its proper light without the despotic action of Rumford. There is every warrant in the circumstances of his temperament and career for this assumption.

A scheme drawn up by Garnett for a full course of lectures in 1801 became a final stumbling-block. At a meeting of the authorities on Feb. 2, 1801, they resolved that the lectures should commence as soon as the new theatre could be got ready for them, and that Count Rumford be authorised "to take all such steps on the part of the managers as shall be necessary in that business", and that Sir Joseph Banks, Henry Cavendish, and Count Rumford act as a committee to superintend the drawing up and publication of a suitable syllabus. It was further resolved that no syllabus of lectures or other account of what is doing or done, or to be done, at the Royal Institution be published by any person or persons without the permission of the aforesaid committee, or the express leave of the managers, signified in writing.

---

* Count Rumford himself had quarters in the Institution's house at this period.

There was thus a fresh stranglehold, and Garnett was unequal to the occasion. On Feb. 16, 1801, the above decisions were communicated to Dr. Garnett, and at the same time it was decided to engage Mr. Humphry Davy as assistant lecturer on chemistry, director of the Chemical Laboratory, and assistant editor of the *Journals*. He was to be allowed to occupy a room in the house, and be furnished with coals and candles. It is noteworthy that both Banks and Rumford were present when these courses were adopted.

THE ROYAL INSTITUTION IN 1800.

A glimpse of internal arrangements in which our forerunners participated may be of interest. Early there were set apart two reading-rooms, in addition, a "Conversation Room". In the former, various scientific periodicals, home and foreign, were available, and it was claimed that effectual measures were in force for securing continental issues without delay; that, indeed, they frequently came to Albemarle Street "whilst yet wet from the press". The "Conversation Room" (so inscribed over the door) was supplied with a collection of maps "to assist agreeable talk". Major James Rennell assisted in this daring venture. Also, it was possible for frequenters to obtain, "at the most reasonable prices", from the housekeeper's quarters below, soups of various kinds, tea, coffee, chocolate, and what were euphemistically designated "other refreshments".

The clerk was enjoined to be constantly provided with writing-paper of all kinds, and pens and ink. As to letters, these were taken away every evening for the General Post, by a postman who, at stated hours, was wont to pass along the street with a clanging bell to proclaim his mission. The Royal Institution paid the postman one guinea a year for call services in lieu of the usual allowance of one penny for each letter, and hence it was not necessary for members to put money into the hall post-box with their letters. Such, then, were the postal and other facilities enjoyed at the Royal Institution in 1800.

In 1801, Count Rumford reported that a complete kitchen for a small family, with a roaster of simple construction, a cottage fireplace grate, and a small boiler with steamers had been installed in the housekeeper's room, and these could be examined by callers. A principal kitchen was promised of larger order, to contain many novel fixtures, and to be open for demonstrations. The merit of any new method of cooking or of any new prepared dish might be judged from the actual experiment. Accordingly, a dining-room was in view in which the managers might order "experimental dinners" to which the proprietors and subscribers could be invited; the attendant expense to be defrayed by "those who partake of them".

In this year, too, as if through other hands, mention is made of the provision of some elegant bookcases, intended to shelve the library gifts of friends of the Institution. The managers welcomed donations, save works of professedly political tendency; whilst in each volume entry was made of the name of the donor, and date, on the ground that "it was agreeable to the principles of justice and to those of an enlightened policy not to forget acts of generosity". The *Journal* for 1802 contains an interesting classified catalogue of the library thus far established.

YOUNG AND DAVY.

In July 1801, Dr. Thomas Young, fortified with the recommendation of Sir Joseph Banks, and reported by Count Rumford as "a man of abilities equal to these undertakings", was instituted professor of natural philosophy, editor of the *Journals*, and superintendent of the house, with rooms. Rumford went elsewhere, but his control was not withdrawn. Young had been elected a fellow of the Royal Society in 1794, at the early age of twenty-one years. His reputation in the world of science and also in Egyptian hieroglyphics is well known.

Young did not remain long in his post, resigning in 1803. It has been handed down, on authority, that he was not successful as a lecturer to mixed audiences. A medallion in Westminster Abbey by Chantrey commemorates this gifted man. It is regrettable that Young is not represented at the National Portrait Gallery.

By this time many of the original schemes projected by Rumford, in particular the applications of science to domestic purposes, had suffered eclipse, through engendered passive resistance or chill indifference, and his authority and influence had waned. The school of mechanics, the workshops, the models, the kitchens became receding propositions—the lectures, laboratory, and library emphasised the Institution. The charter of a new and revised establishment awaited, however, the vision and genius of Humphry Davy. But if the old principles had been worn threadbare, they died hard. Thus, Banks to Rumford (1804): "It [the Royal Institution] is now entirely in the hands of the profane. I have declared my dissatisfaction at the mode in which it is being carried on, and my resolution not to attend in future." Again: "The Institution has irrevocably fallen into the hands of the enemy, and is now perverted to a hundred uses for which you and I never intended it. Adieu, then, Institution!" We realise that the parting of the ways had been reached. From the very start Banks had been a constant supporter of

Rumford, though it is hard to believe that he passed all the coin as sterling.

Humphry Davy was knighted in 1812, created a baronet in 1818, and was elected president of the Royal Society in 1820, following Wollaston. Drastic and fundamental changes in the management of the Royal Institution came about during Davy's time. They were consequent on his discoveries, his lectures, his outlook. There were many obstacles, many critics, and much need for philosophical serenity. In 1809 a report stated that "if the support of scientific men is to be obtained something must be done to give the Institution more the form of a public establishment than that of private and hereditary property". It was not long before the decision was taken to seek parliamentary authority for an Act for altering and amending the charter. This received the Royal assent in 1810. A lecture, comprehending a new plan, by Davy, left nothing unsaid. We quote from his words:

> Besides the diffusion of knowledge by popular philosophical lectures, and by other more elementary and more scientific lectures, the new plan will also embrace a design for the promotion of knowledge by experiments and original investigations.

Sir Humphry Davy married in 1812, and on April 5, 1813, he resigned the post of professor of chemistry and director of the Laboratory of the Royal Institution. It is recorded that on his resignation:

> Earl Spencer moved: That the thanks of this meeting be returned to Sir Humphry Davy for the inestimable services rendered by him to the Royal Institution. The motion was seconded by the Earl of Darnley and agreed to unanimously.

Davy's merits were recognised further by his election as honorary professor of chemistry.

FARADAY.

Michael Faraday, born in London in 1791 (which, as a matter of historic coincidence, was the year which marked the creation of Sir Benjamin Thompson, at the hands of the reigning Duke of Bavaria, Count von Rumford), sprang from the ranks of the humbler classes. His father was a working blacksmith, whose home, Jacob's Well Mews, when Faraday was a small child, was within a quarter of an hour's northerly walk of Albemarle Street. Drawn from a family of select and positive religious fervour, traits of this character tinctured the whole of Faraday's ultimate outlook on life and its obligations. Once he wrote, "In my intercourse with my fellow-creatures, that which is religious and that which is philosophical have ever been two distinct things".

Faraday was equipped only with a scanty day-school education, but he had an inquiring mind, strongly imbued in quite early youth with a love of books and what they could teach him; moreover, he was full of curiosity regarding the very popular scientific discoveries of the period. We hear of his attendance at elementary philosophical lectures in his locality, and of making, in spare moments, simple experiments in chemistry and in electricity.

A member of the Royal Institution—a Mr. Dance —occupies a niche in history, for it was through his good offices that Faraday was enabled, by the merest friendly acquaintanceship extended to a frank, industrious, eager youth, to attend four of Sir Humphry Davy's last lectures in the theatre at Albemarle Street. Highly interested in all he saw and heard at these discourses, during which he made notes, and encouraged further by the same friend, he sent the script to Davy. The reply was encouraging. Faraday was then engaged in bookbinding work, and he had been able to secure some occupation in writing or copying from Davy at a time when the professor was injured in one of his eyes by an explosion of the lately discovered nitrogen chloride. Later on, Faraday himself did not escape the results of explosions. In the year 1812, on Christmas Eve, there came a letter from Sir Humphry. In it he said:

> I am far from displeased with the proof you have given me of your confidence, and which displays great zeal, power of memory, and attention. I am obliged to go out of town, and shall not be settled in town till the end of January; I will then see you at any time you wish. It would gratify me to be of any service to you; I wish it may be in my power.

In the following year matters took better shape. The post of assistant in the Laboratory had become vacant and Davy offered it to Faraday at a wage of 25*s*. a week, with two attic rooms at the skyline of the house. He was introduced to the managers as one of good habits, active and cheerful in disposition, and intelligent in manner. His duties were to assist the various lecturers and professors in preparing for, and during lectures; and he had instructions regarding cleaning, care of apparatus, models, and so on. Though only twenty-one or twenty-two, he seems to have held a watching brief amongst the faithful, little realised, we may be sure, by those on the floor of the theatre. Writing to a friend, he said:

> The opportunities that I have had of attending and obtaining instruction from various lecturers in their performance of duties attached to their office, has enabled me to observe the various habits, peculiarities, excellencies, and defects of each of them, as they were evident to me during the delivery. I did not wholly let this part of the things occurrent escape my notice; but, when I found myself pleased, endeavoured to ascertain what had affected me; also, when attending to Mr. Powell or Mr. Brande in their lectures, observed how the audience were affected, and by what their pleasure and their censure was drawn forth.

Faraday left England in the autumn of 1813 in order to accompany Sir Humphry and Lady Davy on a European tour. They travelled in France, Italy, Switzerland, and the Tyrol, returning to London in April 1815. Re-engagement at the Royal Institution as assistant in the Laboratory happily followed, on increased monetary terms, and with apartments. On June 12, 1821, residence in the Institution having been arranged, Faraday married. In 1824 fellowship of the Royal Society was attained; also, in this year he joined the Geological Society, having interest probably more on the mineralogical side of the science than any other. Later, he served on its council. The outstanding event of 1825 was his election at the Royal Institution as director of the Laboratory and superintendent of the House; in that year, too, came his memorable discovery of benzene, announced to the Royal Society in a paper dated June 16, 1825.

By the time he was thirty-eight (1830), Faraday had accomplished a full measure of practical research. He was, moreover, on the threshold of establishing a physical link, namely, the connexion between electricity and magnetism. But he was ever alive to the needs of the Institution as a corporate body, and of its traditions. He kept continually in mind that the Royal Institution had objects of national importance to carry out; that it required sustaining energy, must be efficacious, and maintain its position, well defined years back by Davy. Apart from research, a great debt of gratitude for fulfilment is due therefore to Faraday, and must be part of the festival of thanks.

The inauguration of juvenile lectures and the discourses at Friday evening meetings were features of this period. At the former, those young people who cared to remain found Faraday ready to talk and explain. He had ease of his own in descending from the topmost rung of the ladder of science to convey in the minds of youthful listeners the scientific principles of 'common things'.

Faraday's connexion with the Royal Society was, of course, close and distinctive. He was a member of council in 1830 when the choice for the chair lay between H.R.H. the Duke of Sussex and Sir John Herschel, the astronomer and physicist. In 1832 and again in 1838 he received the Copley medal for his discovery of magneto-electricity and for researches in specific electrical induction respectively. Royal medals were allotted to him in 1835 and 1846, also the Rumford medal (1846). He was on five occasions Bakerian lecturer. On the last of these (1857) the subject was "Experimental Relations of Gold (and other metals) to Light". His final contribution to the Society was "On Regelation", read on April 26, 1860. In this he referred to the work of Tyndall and others. The Royal Society invited him to be its president in succession to Lord Wrottesley, but he stood aside in fixity of purpose. Visitors at the forthcoming centenary celebrations will be able to see at the rooms of the Royal Society the canvas by E. Armitage, R.A., portraying a deputation thereon, in 1857.

As scientific adviser to the Trinity House for a long series of years, Faraday made numberless reports, and paid constant visits to lighthouses.

In 1861, when sixty-nine years of age, Faraday conceived that the end of his scientific pilgrimage was within sight. Hence, writing to the managers of the Royal Institution, he reminded them of forty-nine years' service. His life had been a happy one, and all he desired. In its progress he had tried to make fitting return to the Royal Institution, and through it to science. The course of time had given development, maturity; now he had to face gentle decay. The managers, however, desired his retention of office in such manner as might appear convenient to himself.

In 1866 Faraday received from the Society of Arts its Albert medal—"for discoveries in electricity, magnetism, and chemistry, which, in their application to the industries of the world have largely promoted Arts, Manufactures, and Commerce". This was, in all probability, the last British recognition of his achievements that life permitted him to receive. The Prince Consort, in compliance with the wishes of Queen Victoria, had placed a house at his disposal on Hampton Court Green. There Faraday died on Aug. 25, 1867.

TYNDALL.

John Tyndall was a moving figure in philosophy and in those manifold applications of science which distinguished the nineteenth century, tokens of newness of ideas and newness of things. Chosen in May 1853 to be professor of natural philosophy at the Royal Institution, he was a colleague of Michael Faraday for fourteen years. In 1867 he succeeded the master at Albemarle Street, and his future career lay there, embracing in all thirty-four years. Throughout, he maintained a high reputation as a lecturer, writer, and publicist.

Tyndall was born in Ireland in 1820. His early education, though restricted, was broadly amplified through intensive individual effort. He was at the University of Marburg from 1848 until 1851. About this period a lifelong friendship began with T. H. Huxley. The publication of an essay on the cleavage of slate rocks was the proximate cause of his joining the latter in a visit to the glaciers of Switzerland in 1856; they issued afterwards a joint paper on the structure and motion of glaciers. For some years Tyndall was scientific adviser to the Trinity House and the Board of Trade, but he resigned these offices in 1883. Elected a fellow of the Royal Society in 1852, he received the Rumford medal in 1864; and he was on four occasions Bakerian lecturer.

At his first Friday evening lecture at the Royal Institution, delivered on Feb. 11, 1853, Tyndall remarked that he had engaged in it "not without fear and trembling, for the Royal Institution was to me a kind of dragon's den where tact and strength would be necessary to save me from destruction". Many words of wisdom have been uttered from behind the lecture table of the Royal Institution. Words of Tyndall uttered in 1879, in a discourse on the electric light, are singularly appropriate to recall just now—"it is Faraday's spark which now shines upon our coasts, and promises to illuminate our streets, halls, quays, squares, warehouses, and, perhaps at no distant day, our homes".

Tyndall died at Hindhead, near Haslemere, on Dec. 4, 1893.

Faraday's London Friends.

By H. G. Wayling.

FARADAY was essentially a Londoner. Although he was born on the south side of the Thames, he spent the greater part of his life in the northern districts between Regent's Park and Oxford Street, or at the Royal Institution in Albemarle Street, Piccadilly. From the following addresses of some of his scientific acquaintances the metropolis of his day becomes alive again. To visit all these highways and byways on foot would certainly be a tiring tramp. Failing, however, the use of a motor car, all the thoroughfares may be found on any good map of London.

One of the founders of the Royal Institution was Sir Joseph Banks, who lived at No. 32 Soho Square, a little west of Charing Cross Road. He died in 1820, so that Faraday would only know him as a gouty old autocrat. At the same house resided Dr. Robert Brown, amanuensis and librarian to Sir Joseph. Brown became one of the leading botanists in Europe, and sealed his claim to scientific recognition by the discovery of the Brownian movement, a topic which Faraday selected for one of his popular lectures at the Royal Institution. South of Regent's Park and parallel to Portland Place is Charlotte Street, where William Nicholson died. In conjunction with Sir Anthony Carlisle, who dwelt not more than a stone's throw away at No. 6 Langham Place, he effected the decomposition of water electrolytically. As the experiment was carried out at the Royal Institution in 1800, Faraday would know these co-workers, when in a few years later he became interested in the study of natural philosophy.

Still farther west and south of Regent's Park is Baker Street, a name well known to readers of Sherlock Holmes. Crossing it at right angles is Dorset Street, where, at No. 1, lived William Hyde Wollaston and, after him, Charles Babbage. The former, who was the interim president of the Royal Society, after the death of Sir Joseph Banks, was of the opinion that a wire carrying an electric current has a tendency to rotate on its axis; but Faraday, who watched Wollaston's unsuccessful attempts to achieve this feat, succeeded in making a similar wire revolve round the pole of a magnet. When Babbage became the tenant of the house in Dorset Street, he entertained extensively. John Dalton stayed here when he came from Manchester to lecture at the Royal Institution, where Faraday at the rehearsal of these discourses acted as audience and critic all in one. Among other guests of the inventor of the calculating machine was Sir David Brewster, who occasionally left the capital of the north to visit that of the south. Branching off Baker Street is Blandford Street, where Faraday worked as a bookbinder's apprentice.

Not far from here and in a south-easterly direction is Cavendish Square, connected to Oxford Street by a short thoroughfare called Holles Street. In this byway lived Davies Gilbert, a close friend of Davy and his successor to the presidency of the Royal Society. As practically every prominent member of that distinguished society would at one time or another pass through the doors of the Royal Institution, then their research laboratory, Faraday would experience the force of the saying, "the friends of thy friends are my friends." As chairman of the Royal Institution for a recognised period, Charles Hatchett would be another of Faraday's acquaintances. Hatchett was a mineralogist of some distinction, and incidentally, the father-in-law of W. T. Brande, who succeeded Davy as professor of chemistry at the institute in Albemarle Street. Hatchett lived in his later years in Lindsey Row, Chelsea; a terrace of big houses facing the river. Brande was born in Arlington Street, a southern tributary of Piccadilly.

Mrs. Marcet, whose "Conversations on Chemistry" whetted the youthful appetite of Faraday for experimental science, lived in Great Coram Street, Russell Square. Her tea parties were well patronised by several fellows of the Royal Society. Berzelius tasted her hospitality and Maria Edgeworth at times assisted her in these social amenities. Among Faraday's friends were many Quakers. William Allen, who resided in Plough Court, Lombard Street, was one of them. The firm of Allenbury is still in possession of the premises. Allen lectured before the Royal Society, and like most adherents of his particular faith, was earnest in all good works. Another, whose name is among the most notable who have lectured at the Royal Institution, was Thomas Young. Although a member of the Society of Friends, he modified his tenets and comportment with the changing times. This remarkable genius dwelt at No. 48 Welbeck Street, parallel to Harley Street, as befitted a physician of his social status. Then there were William and Richard Phillips, the sons of a publisher in George Yard, Lombard Street. They were fellows of the Royal Society and also prominent members of the Geological Society. It was Richard Phillips who induced Faraday to undertake public analytical work to augment his slender income.

William Haselden Pepys was another Quaker. He kept an instrument-maker's shop in the Poultry, also not far from Lombard Street, being, like many other of his co-religionists, within easy access of the Friends' meeting house in Gracechurch Street. When young Faraday wrote to Davy requesting that a situation might be found for him in the Albemarle Street laboratory, Sir Humphry showed the letter to Pepys and asked for his advice. "Set him to wash bottles" was the reply; a suggestion that Davy did not think worth accepting. Davy lived at No. 26 Park Street, Grosvenor Square, that is, in Mayfair, where his aristocratic wife entertained in great style. A more modest acquaintance of the subject of our theme was Peter Mark Roget, whose electrical jumping spiral may still be seen in the Science Museum at South Kensington. He lived at No. 18 Upper Bedford Place, just north of Russell Square, Bloomsbury. As secretary of the Royal Society, Roget had intermittent correspondence with Faraday—in particular, that on the manufacture of optical glass.

The mention of this topic reminds us that we might cross the river for a change, passing over London Bridge and proceeding down the Borough High Street. Along this route we enter Newington Causeway, once called Blackman Street. Here Sir James South had an observatory and laboratory. With the assistance of Sir John Herschel, he undertook the manufacture of various kinds of glass; and it was a modified form of this experimental ware, containing lead borate, that Faraday employed in his investigations on the relationship between magnetism and polarised light. Mr. Rollo Appleyard, in his recent biography, tells us that Sergeant Anderson, who acted as general factotum to Michael Faraday at the Royal Institution, served his apprenticeship in Sir James South's laboratory in Blackman Street. A short distance ahead is Newington Butts, where the great natural philosopher himself was born.

Returning to the neighbourhood of Oxford Street, where so many of his admirers lived, we pay a call to Hanover Square, which is on the other side of the road to Cavendish Square. At No. 12 resided Mrs. Mary Somerville, a frequent visitor to the Royal Institution. As there is a memorial plaque on its walls, the building can be easily identified. Mrs. Somerville relates that Wollaston, one day, in his usual quiet mysterious way, closed the shutters of her drawing-room; then holding a glass prism in the path of a beam of light that came in through a chink, exhibited to her the dark lines of the solar spectrum. Sir Charles Lyell met his future wife at one of Mrs. Somerville's dinner parties, and when he set up housekeeping he lived for many years at 53 Harley Street, only a few steps away. Lyell accompanied Faraday to investigate the cause of a terrible explosion that occurred at Haswell Colliery, Durham. During his local inquiries Faraday was shocked to find that the foreman of the mine demonstrated some of the tragic details with a lighted candle in his hand, having thoughtlessly given the professor himself a sack of gunpowder on which to sit and watch the demonstrations.

Among the familiar portraits of Faraday is one in which he appears in company with J. F. Daniell, whose name still persists in a well-known voltaic cell. Daniell was born in Essex Street, Strand. He lectured at the London Institution, Finsbury Circus, a rival academy to that off Piccadilly.

Dr. J. A. Paris, the biographer of Davy, was also well acquainted with Faraday. On one occasion when Paris paid a visit to Faraday's laboratory, he criticised adversely the apparently filthy appearance of some of the glass tubes. The next morning a short note was left at the doctor's house, No. 27 Dover Street, containing this laconic statement: "the 'oil' you noticed yesterday, turns out to be liquid Chlorine".

Part of his time Faraday lectured at Woolwich Academy. Here he co-operated with S. H. Christie, a Londoner—born at No. 90 Pall Mall; with Peter Barlow, whose familiar wheel is a type of electric motor; with the chemist Marsh, on whose test for arsenic all analysts rely; and with William Sturgeon, who was the first to use soft iron in the construction of electromagnets. Faraday's first biographer, Dr. Bence Jones, lived in Brook Street, Grosvenor Square. Being the secretary of the Royal Institution, Jones would have exceptional opportunities of knowing his subject both in private and public life. Another of his biographers and close friend was Dr. J. H. Gladstone. He was by marriage related to Lord Kelvin, who accepted his relative's hospitality at No. 17 Pembridge Square, Notting Hill, whenever he could be induced to leave his professorial duties in Glasgow.

The British Association Centenary Meeting.

THE centenary meeting of the British Association will be formally opened on Wednesday next, in the Albert Hall, at 3 P.M., when the Right Hon. J. C. Smuts will assume the presidency in succession to Prof. F. O. Bower, and will receive the invited delegates of societies and institutions, and of universities, colleges, and cities in which the Association has held meetings in the past. On the second day, in the Central Hall, Westminster, at 9 P.M., General Smuts will deliver his presidential address on the subject of "The Scientific World-Picture of To-day".

General Smuts will ask, in his address, what the effect of the recent scientific advances is on our conception of the world. On one hand, we have the ordinary common-sense view of the world, which is based on practical experience and tradition but does no longer square with the principles of science. On the other, we have the scientific world-view of the last century, which left the common-sense nature of the material world essentially unaffected, but could find no proper place for the factors of life and mind, and which thus reduced the world to the picture of a fixed deterministic mechanism. Both common sense and mechanistic science are profoundly affected by the new physical concepts, especially those of space-time and the quantum and their consequences. Matter, in the old sense, is completely transformed, and immaterial electrons and radiations take its place as the substance of the world. Our whole view of the nature of the material world seems to be upset and revolutionised.

Building on these great discoveries, a new world-view has recently arisen which yet, like the older science, emphasises almost exclusively the physical measurable aspects of the world. The world is constructed into a system of mathematical symbols. Matter, in the old sense, having disappeared, the world is made out to be a highly abstract intellectualised shadow world. On this view, however, a world emerges which cannot in any sense be considered real or possess any attribute of power or dynamic quality.

While acknowledging the enormous advance made by physics recently, it is suggested by General Smuts that it would be a mistake to emphasise them exclusively, and that the older concept of organic evolution is no less important for our world-view. The relations between the new concepts of space-time and the quantum on one hand, and those of life and mind on the other, are therefore discussed, and an attempt is made to connect up the system of the new physics with that of organic evolution. By thus avoiding the merely physical view of the world and linking it up with the facts of biology and psychology, which are equally valid with those of physics, a world-view results which, while destructive of the common-sense view of matter, also differs from both nineteenth-century mechanism and the more recent mathematical symbolism. It is shown that this is an evolutionary universe, essentially genetic and holistic; that it has passed through various phases from its microscopic origins to its present macroscopic status; and that inside this macroscopic system the phase of life and mind is emerging as a new high level in the universe. It is finally suggested, as a result not only of organic evolution but also of the new physics, that the essential character of the universe does not preclude new creation, and that there are indications of a certain measure of free movement and creativeness throughout the world which increases in life and mind and in the emergence of new values. Within the deterministic limits of the universe the human spirit may thus have an assured status and a certain measure of creative free play.

General Smuts's address will be published in full in a Supplement to next week's issue of NATURE, together with summaries of the addresses of the presidents of Sections of the Association. The programmes of the Sections, including the subjects of the presidential addresses, were given in our issue of Aug. 8. In addition to several discussions of high scientific importance there mentioned, the evening discourses to be delivered during the meeting are of particular interest. Sir James Jeans will take as his subject " Beyond the Milky Way " ; Sir Oliver Lodge, " A Retrospect of Wireless Communication " ; Sir Arthur Keith, " The Constitution of Man's Family Tree " ; Sir P. Chalmers Mitchell, " Zoos and National Parks " ; and Dr. S. Kemp, " Oceanography in the Antarctic ".

Special facilities will be offered for visits to a number of public resorts of scientific interest ; and these include the Royal Botanic Gardens, Kew, where the director, Sir Arthur Hill, is arranging an exhibition of plants named after botanists, with portraits of the botanists themselves. The exhibit will be placed in the alpine house at the end of the herbaceous ground. An exhibit of this character should be of general interest, since it will serve to explain the somewhat obscure generic names of a number of well-known plants. In the limited space, it is not possible to have a fully comprehensive exhibit, but a selection will be made of well-known plants named after distinguished botanists and travellers. Among them will be found the Swedish creeping plant *Linnæa*, allied to the honeysuckles, which was named in honour of Linnæus and was the favourite plant of the great naturalist ; the *Dahlia*, which was named after Dr. Andrew Dahl, the Swedish botanist who was a pupil of Linnæus (Dahl brought this favourite garden plant into cultivation, but unfortunately no portrait of him appears to exist) ; *Matthiola*, the stock named in honour of Pietro Matthioli (1500–1577) ; *Lobelia*, named after Mathias de Lobel (1538–1616) ; *Cunninghamia*, after Richard and Allan Cunningham ; *Darwinia*, commemorating Erasmus Darwin, the father of Charles Darwin ; *Gesnera*, after Conrad Gesner ; *Eschscholzia*, which was named after the botanist Dr. Eschscholtz ; *Cinchona*, which bears the name of the Countess Chinchon, the wife of the Viceroy of Peru, to whom the introduction of the knowledge of the drug is usually ascribed ; *Camellia*, named in honour of George Joseph Kamel, who travelled in the East ; *Magnolia*, named after Pierre Magnol (1638–1715), professor of medicine at Montpellier ; *Tradescantia*, named after John Tradescant (died 1638), who was gardener to Charles I. ; *Sparmannia*, the well-known South African plant, which was named after Dr. A. Sparmann, the Swedish botanist who accompanied Capt. Cook on his second voyage round the world and introduced this well-known greenhouse plant to cultivation ; *Fuchsia*, named in honour of Dr. Leonard Fuchs (1501–66) the author of the celebrated " Herbal " ; and *Kniphofia*, the " Red Hot Poker ", named after Johann Hieronymus Kniphof (1704–1763), a professor of medicine at Erfurt.

A very large number of delegates and other visitors from abroad are attending the meeting. Many of these are presenting papers or taking part in discussions in the various sections, among them being the following :

Section A : Dr. J. Bjerknes, Bergen ; Prof. A. S. Eve, Montreal ; Dr. H. Spencer Jones, Cape Town ; Prof. J. C. McLennan, Toronto ; Prof. M. N. Saha, Allahabad ; Prof. F. Schlesinger, New Haven ; Dr. B. F. J. Schonland, Cape Town ; Prof. W. de Sitter, Leyden ; Prof. P. Zeeman, Amsterdam.

Section B : Prof. N. J. Bjerrum, Copenhagen ; Prof. J. N. Brønsted, Copenhagen ; Prof. P. Debye, Leipzig ; Prof. H. von Euler-Chelpin, Stockholm ; Prof. V. Henri, Marseilles ; Prof. P. Karrer, Zurich ; Prof. R. Kuhn, Heidelberg ; Prof. H. Wieland, Munich ; Prof. A. Windaus, Göttingen.

Section C : Prof. H. A. Brouwer, Delft ; Prof. J. W. Jongmans, Heerlen ; Prof. P. Niggli, Zurich ; Prof. P. D. Quensel, Stockholm ; Dr. E. O. Ulrich, Washington.

Section D : Prof. H. Fairfield Osborn, New York.

Section E : Prof. J. H. Wellington, Transvaal ; Prof. W. Werenskiøld, Oslo.

Section F : Edgar Atzler, Berlin ; Dr. Hermuth Boller, Vienna ; R. L. Hall, Grahamstown ; Pierre Jolly, Paris ; Henri Laugier, Paris ; Dr. Elton Mayo, Massachusetts ; Dr. H. S. Person, New York.

Section G: Brig.-Gen. C. H. Mitchell; Dr. Elihu Thomson, Lynn, Mass.

Section H: Dr. R. Broom, Douglas, S. Africa; Dr. H. C. van Riet Lowe, Cape Town; Prof. Sergio Sergi, Rome; Prof. V. Suk, Brno; Dr. G. Thilenius, Hamburg.

Section I: Prof. Frank Allen, Manitoba; Dr. R. Alexander, Pretoria; Prof. D. W. Bronk, Pennsylvania; Dr. C. K. Drinker, Harvard; Prof. Yandell Henderson, Yale; Prof. C. Heymans, Ghent; Dr. J. M. Rivers, New York.

Section J: Prof. W. Köhler, Berlin; Prof. H. Piéron, Paris.

Section K: Prof. F. E. Lloyd, Montreal.

Section L: Prof. F. Clarke, Montreal; the Hon. S. Rivers Smith, Tanganyika.

Section M: Dr. W. Lawrence Balls, Giza; Dr. D. J. Hissink, Groningen.

Among other visitors from abroad whose names do not appear in the handbook and time-table of the sectional meetings, but who will probably take part in some of the proceedings, we notice the following: Dr. C. G. Abbot, Washington; Prof. Max Bodenstein, Berlin; Prof. Niels Bohr, Copenhagen; Prof. A. H. R. Buller, Manitoba; Dr. J. McKeen Cattell, New York; Prof. R. Chodat, Geneva; Prof. E. J. Cohen, Utrecht; Prince Conti, Florence; Baron de Geer, Gothenburg; Prof. W. K. Gregory, New York; Prof. W. Heisenberg, Leipzig; Prof. G. Hevesy, Freiburg; Prof. A. E. Kennelly, Harvard; Prof. J. P. Lotsy, Velp; Prof. A. B. Macallum, London, Ont.; Senatore Marconi, Rome; Prof. R. A. Millikan, Pasadena; Dr. Th. Mortensen, Copenhagen; Dr. H. Nagaoka, Tokyo; Prof. J. Perrin, Paris; Dr. H. M. Tory, Ottawa; Prof. R. Willstätter, Munich; Prof. R. W. Wood, Baltimore.

International Union of Physics, Brussels Meeting, 1931.

A MEETING of the International Union of Physics was held in Brussels on July 12, and was attended by representatives of about fourteen countries. Prof. Gerlach, of Munich, and Dr. Rupp, of Berlin, were also present by the invitation of the president. A revised set of statutes, prepared by the executive committee, was considered and passed.

At the previous meeting of the Union an invitation had been given to hold a meeting in England so soon as it was possible for all nations to take part. Sir Richard Glazebrook, as representing Great Britain, expressed his pleasure that, under the new statutes, this condition was now satisfied, and cordially welcomed the German visitors to the meeting. He then renewed the British invitation, saying, however, that he had been informed that there was a very strong desire that the Union should visit America on the occasion of the Chicago Exhibition in 1933, and that it was for the Union to decide. A telegram was then read from Prof. Millikan, cordially inviting the Union, and this invitation was strongly supported by Dr. Kennelly and Dr. Schlesinger, the American delegates.

After some further discussion, the General Assembly of the Union decided unanimously to accept the invitation to Chicago, and to invite Prof. Millikan to become president of the Union in succession to Sir William Bragg, whose term of office had expired.

Discussion then followed on matters brought forward either by national committees or by individual physicists. Among these were the proposals of the British National Committee as to the definition of the calorie and a name for the unit of thermal conductivity, and of M. Cotton as to names for magnetic units. As the result of the discussion, a sub-committee was appointed to deal with symbols, units, and nomenclature in physics and to report to the General Assembly. At the first meeting of this sub-committee, held on July 12, Prof. Kennelly in the chair, the following resolution was agreed to unanimously:

> That this Commission recommends to the Executive Committee of the International Union of Physics that the following two propositions be communicated to the next General Assembly as recommendations from this Commission.
>
> 1. That the Unit of Heat when measured in units of energy be the Joule, defined as equivalent to 10^7 ergs.
> 2. That the gramme-calorie is the amount of heat required to raise the temperature of one gramme of water from 14·5° to 15·5° of the International Scale of Temperature.
>
> *Note on Proposition* 2.
>
> "According to existing measurements, the gramme calorie is equivalent to
>
> $4{\cdot}18_6$ Joules.
>
> "The definition is consistent with the decision of the International Steam Tables Conference in 1929 to adopt as a unit suitable for their purpose an International Kilocalorie equivalent to 1/860 of an International Kilowatt Hour, the difference being that between the Absolute Watt* and the International Watt."

---

* International Watt = 1·00039 Absolute Watts.

Obituary.

Sir Thomas Stanton, C.B.E., F.R.S.

THE death at Pevensey Bay on Aug. 30 of Sir Thomas Ernest Stanton tragically ended a distinguished career largely devoted to the service of the State. He was one of the greatest research engineers Great Britain has produced, and a worker whose name will rank with those of Rankine and Osborne Reynolds, under the latter of whom he studied and carried out some of his early work.

Sir Thomas, who was sixty-five years of age, had retired in December 1930 from the post of superintendent of the Engineering Department at the

National Physical Laboratory at Teddington, a position he had occupied for nearly thirty years. Born on Dec. 12, 1865, the son of Thomas Stanton of Atherstone, he was educated at Atherstone and Manchester Grammar Schools, whence he proceeded to Owens College, where, after experience with Messrs. Gimson and Co., engineers, of Leicester, he was appointed demonstrator by Osborne Reynolds in the Whitworth Laboratory, a position he held for five years.

In 1896, Stanton removed to Liverpool, on appointment to the senior lectureship in engineering at University College. Three years later he became professor of civil and mechanical engineering at Bristol, a position he held until 1901, when he joined the staff of the National Physical Laboratory, which was then in the earliest stages of its development.

Stanton proceeded to build up the Engineering Department to its present position of eminence. Few have exerted a wider influence in the application of laboratory methods to engineering problems. For some years he was also in charge of the aerodynamical work of the Laboratory. His personal researches covered an extensive field, including the study of wind pressures on structures, the resistance of materials to intermittent stresses, lubrication, the heat-transfer and friction between solid surfaces and moving fluids, and the movement of projectiles at speeds exceeding the velocity of sound. These and other researches have formed the subject of numerous papers presented during the past thirty years to the Royal Society, the Institution of Civil and Mechanical Engineers, and the more important engineering journals. His book on "Friction" (1923) is also very widely known. So recently as May last he delivered the thirty-seventh Sir James Forrest Lecture, on "Engineering Research," before the Institution of Civil Engineers.

Stanton was admitted a fellow of the Royal Society in 1914 and served on the Council during 1927–29. He was a D.Sc. of the University of Manchester, a fellow of the Royal Aeronautical Society, and a member of the Institutions of Civil and Mechanical Engineers. For his work in the War he received the C.B.E. in 1920 and he was knighted in 1928.

Despite a somewhat retiring disposition, Stanton's advice was much sought, for it was known to be kindly, sound, and sagacious. He was genial and unassuming, and his popularity with his colleagues was amply evinced on the occasion of his retirement from the Laboratory. During the past year his life had been clouded by ill-health. He married in 1912 a daughter of Mr. John Child, of London, and he leaves, besides Lady Stanton, a daughter aged eighteen years and a fourteen-year-old son, to whom we offer our deep sympathy.

Dr. L. W. Sambon.

It is with deep regret that we have to record the sudden death of Dr. L. W. Sambon in Paris on Aug. 31. By his death a striking personality has passed away.

Sambon was born in Italy in November 1865. He was of Anglo-French parentage, his father being Comm. Jules Sambon, an antiquarian and numismatist of repute, and his mother an Englishwoman. He was educated in England and Switzerland, and later studied medicine at St. Bartholomew's Hospital Medical School and in the University of Naples, where he took his medical degree.

From an early age Sambon took great interest in numismatics, archæology, natural history, and volcanology. As a medical student, he rendered valuable service during the great cholera epidemic in 1884, and was awarded for his work bronze and gold medals by the Italian and French Governments. In 1897 he settled in London, where he devoted himself to medical research at a time when tropical medicine was almost in its infancy. His first article on "Acclimatisation of the White Man in Tropical Lands" roused a great deal of controversy, but it had a good effect. It brought him in contact with Manson, who was at that time Medical Adviser to the Colonial Office, and their association was interrupted only by the death of Manson.

In the summer of 1900, Sambon carried out the now classical malarial experiment in the Roman Campagna (Ostia) with Dr. George C. Low and one of us (T.).

Sambon was for many years a lecturer at the London School of Tropical Medicine. He published many papers on sunstroke, blackwater fever, malaria, sleeping sickness, pellagra, typhoid, schistosomiasis, and so on. He was at the time of his death carrying out investigations on cancer, in Westmoreland—a subject on which he had already published several reports. He wrote much on the history of medicine. He studied the surgical instruments of ancient times and utensils found in Roman graves, and his interpretations of these relics have thrown considerable light on the medical knowledge of past ages.

Sambon has been called volcanic, he has been accused of being a dreamer and a visionary, but whatever theories he may have advanced, which may have been at the time considered far-fetched, those theories undoubtedly fertilised the fields in which he worked.

A. J. Engel Terzi.
S. Maulik.

We regret to announce the following deaths:

Dr. Aristides Agramonte, president-elect of the Pan-American Medical Congress, known for his work on bacteriology in Cuba, who associated himself with the work of clearing the Panama Canal zone of disease, aged sixty-two years.

Prof. Errol Lionel Fox, professor of chemistry at Washington College, Chesterton, Maryland, on July 17, aged thirty-eight years.

Dr. Russell A. Oakley, principal agronomist in the Division of Forage Crops and Diseases of the Bureau of Plant Industry, United States Department of Agriculture, on Aug. 6, aged fifty-one years.

News and Views.

THE celebration of the centenary of the birth of James Clerk Maxwell is to be held in Cambridge on Oct. 1 and 2, following immediately on the Faraday celebrations and the British Association meeting. About ninety delegates have been nominated by the principal academies and learned societies of the world and by the home universities. Amongst the delegates are Profs. Kennelly and Millikan from the United States; Profs. Cotton and Brillouin from France; Prof. Max Planck, Prof. Debye, Prof. Bohr, Prof. Siegbahn, His Excellency the Marchese Marconi, General Smuts, Prof. Zeeman, and Prof. Nagaoka. The University of Cambridge has also invited a number of guests and will have the pleasure of welcoming at the celebration many of those who worked in the Cavendish Laboratory in its first years under Maxwell—Dr. William Garnett, Sir Ambrose Fleming, Sir Richard Glazebrook, Sir Napier Shaw, Sir Arthur Schuster, Prof. W. M. Hicks, and others. Before the opening of the celebration in Cambridge, it is expected that many of the delegates will attend the unveiling of memorial tablets to Faraday and Maxwell in Westminster Abbey. The Royal Institution and the University of Cambridge have obtained the permission of the Dean and Chapter for the placing of these memorials, and it has been considered appropriate that they should lie, with the Kelvin tablet, in close proximity to the Newton tomb. The Master of Trinity, Sir J. J. Thomson, will unveil the tablets at noon on Sept. 30.

THE official proceedings in Cambridge of the Clerk Maxwell celebrations open with the Vice-Chancellor's luncheon in Corpus Christi College on Oct. 1. At 2.45 P.M. a procession is to be formed to the Senate House, where the Chancellor will welcome delegates and receive addresses. The Master of Trinity will then deliver the memorial lecture. After this will follow an 'At Home' in Peterhouse, Maxwell's first home in Cambridge, and in the evening a reception will be held in St. John's College. On the morning of Friday, Oct. 2, addresses will be given in the Arts School by Prof. Max Planck, Sir Joseph Larmor, and Prof. Niels Bohr. In the afternoon an address will be given in the Cavendish Laboratory by Sir James Jeans, also short addresses by contemporaries of Maxwell: Dr. Garnett, Sir Ambrose Fleming, and Sir Oliver Lodge. An exhibition of Maxwell apparatus and manuscripts is being organised, and visitors will have an opportunity of seeing the work of the laboratory. The proceedings will be closed by a banquet given by Trinity College. The addresses given at the celebration together with a contribution by Prof. A. Einstein are to be published by the University Press in a commemoration volume.

THE National Portrait Gallery has a collection of portrait sketches in pencil on sheets of drawing-paper which includes a head of Michael Faraday, bearing the date 1831. A friendly letter in Faraday's handwriting addressed to William Brockedon is appended. Various other well-known people of the period—for example, Brunel, drawn in the same medium—form a small collection of much interest in contemporary portraiture. Some in the series have received slight additions by coloured chalk in order to enhance the effect. William Brockedon, son of a local watchmaker, was born at Totnes in 1787. He died in London in 1854. He was a painter of repute, an author, and an inventor. In the year 1834, Brockedon was elected a fellow of the Royal Society. In all, he exhibited 36 pictures at the Royal Academy, and 29 at the British Institution. He founded the Graphic Society in 1831, an association of one hundred artists. Also, in 1830, he helped in founding the Royal Geographical Society, and was a member of the first council of that body. As an inventor, Brockedon was well known. One of his patents referred to a substitute for corks, composed of vulcanised india-rubber; another (1843), a process for compressing pure blacklead powder (obtained from Cumberland's dwindling sources) into compact blocks from which lead pencils were afterwards fashioned. Brockedon was the author of "Illustrations of the Passes of the Alps", two vols., 1828–29.

MR. SNOWDEN, Chancellor of the Exchequer of the new National Government, introduced his emergency budget in the House of Commons on Sept. 10 and a White Paper (Cmd. 3952. London: H.M. Stationery Office, 3*d.* net) was issued setting out the proposed reductions in national expenditure. The measures proposed are based largely on the report of the May Committee, reference to which was made in our columns in the issue of Aug. 8. We criticised then the principle of singling out research activities for curtailment, and it is gratifying to find that Mr. Snowden has at any rate mitigated the blow. Whereas the May Committee recommended the abolition of the Empire Marketing Board, it is now proposed to reduce its grant by a quarter of a million; and the suggested reduction of £250,000 in the grant to universities and university colleges has been made £150,000, which, it is explained, will not affect annual grants, in that it represents an accumulated balance normally used for non-recurrent purposes. In other directions, the recommendations of the May Committee have been followed more closely. The vote for the Ministry of Agriculture and Fisheries is to be reduced by £580,000, which involves postponement of new developments for agricultural research and also of the Government grant towards the reconstruction of the Royal Veterinary College. It will also be impossible to operate the new fisheries research ship during 1932. The Colonial Development Fund will be restricted to £750,000, thus saving £250,000; while the expenditure of the Forestry Commission will be reduced by nearly half a million pounds, by restricting afforestation schemes.

THE flood-lighting of London has been criticised on the ground that it is an unjustifiable expenditure of public money at a time when economy should be practised. The cost, however, is being entirely defrayed by certain firms and other bodies connected with the electrical and gas industries. It was originally organised in honour of the International Illumination Congress. The headquarters of the Congress were in London, but meetings were held in several other cities, including Edinburgh and Glasgow. At the Edinburgh meeting, Mr. Clifford C. Paterson, president of the Congress, presented a paper entitled "The British Standard Specification for Street Lighting", which should prove very useful in improving the illumination of many of our streets. Many improvements have been introduced into the 1931 specification. An important point is the introduction of the phrase 'average illumination' into the specification. It is now specified that, in any tender, values must be given of both the maximum and average illumination on the roadway. A great obstacle in the way of starting average illumination is the difficulty hitherto experienced in practice in measuring it. For practical purposes it is now found that it is unnecessary to measure the illumination in the street by means of a photometric device. The data are best obtained by calculation from the known candle-power distribution data of the fitting that is to be used. A graphical method is given of computing the average illumination, and this eliminates much of the laborious arithmetical work involved.

THE eleventh Shipping, Engineering, and Machinery Exhibition being held at Olympia was opened on Sept. 10 by Sir Austen Chamberlain, First Lord of the Admiralty. Referring to the interest and sympathy of the Government in general, and the Admiralty in particular, to the exhibition, Sir Austen remarked that upon no section of enterprise has economic stress fallen more heavily than on those branches of trade, commerce, and industry which are represented in the exhibition. It speaks well, however, for the vital strength of these trades that even in such times they can provide so magnificent and novel an exhibition. The organisers of the exhibition are Messrs. F. W. Bridges and Sons, Ltd., who have the support of the British Engineers' Association (Inc.), the Society of Motor Manufacturers and Traders, Ltd., and the British Marine Oil Engine Manufacturers' Association. The honorary president is Admiral of the Fleet Lord Wester Wemyss, while Dr. H. S. Hele-Shaw is the chairman of the honorary committee of experts. The exhibition will remain open until Sept. 26, and during that time official visits will be paid to it by more than fifty engineering and scientific societies. The exhibits cover a very large field, and there are few which are not, indirectly or directly, the outcome of scientific research.

THERE are altogether some 300 exhibitors at Olympia, and about 40,000 copies of the advanced catalogue, printed in three languages, have been sent all over the world. The official catalogue is on sale at the exhibition at 1*s*., and visitors can from this easily find the position of the exhibits they are most interested in. A classified index is first given, under such headings as electrical machinery and apparatus, engines, gauges, instruments (electrical, navigating, and scientific); this is followed by a list of exhibitors and by descriptions of the exhibits, the latter covering nearly 300 pages, and being given according to the order in which the stands are arranged. How largely scientific instruments have been adopted for the control of engineering processes can be seen by the inspection of the exhibits of the various instrument makers. For example, Messrs. Elliott Bros. (London), Ltd., have on view a collection of heat economy and control apparatus, including automatic boiler control, flue gas analysis, smoke density, and temperature equipment, such as will be found in a modern power station. This exhibit is typical of many others. An exhibit which was attracting much attention on the day of opening was the latest Admiralty type of echo sounding gear with transmitter and hydrophone, made by Messrs. Henry Hughes and Sons, Ltd. But there are many other exhibits of great scientific interest. As the exhibition will remain open until Sept. 26, many visitors to the Faraday Exhibition at the Albert Hall will no doubt also visit Olympia, and we note that an official visit to the exhibition is to be made by the British Association on Sept. 25.

IN his presidential address to the annual conference of the Sanitary Inspectors' Association at Bridlington last week, Sir Leonard Hill directed attention to some problems of population. In Great Britain the annual excess of births over deaths per 1000 living, which was 12 at the end of last century, is now less than 3, so that if the decline continues, soon the population will become stationary. Three children per family are required to maintain the population and make good losses, but no-child or one-child families are becoming the rule among the masses. We ought to be able to send to the dominions and colonies 250,000 young virile emigrants annually, for if the British and Australians cease to breed enough virile colonists to till and defend Australia, how can we stem invasion by the Japanese, who are multiplying at the rate of a million a year? Luxury, decay of virility, doles, the employment of mercenaries, and limitation of breeding has preceded the downfall of empires in the past; yet if kept within bounds, who can doubt that limitation of breeding is an excellent thing? But if the white man is limiting his breeding by birth control, which is now practised in all classes of the community, we must see to it that the coloured races are also taught the method of doing so. At present such races are kept down to the level of the food supply by high infant mortality, famines, and epidemic disease. A less cruel world can only be brought about by a rational limitation of the birth-rate, but this must be coupled with realisation of the duty of keeping up a virile race. At present, unfortunately, the unskilled and less desirable portion of the population continues to breed more than the skilled and better classes.

ON Sunday, Sept. 13, the Institute of Metals began its annual autumn meeting in Zurich and more than two hundred members were present, including about a hundred foreign members from fifteen different countries. This cosmopolitan gathering — presided over by Dr. Richard Seligman—considered twenty-five important original communications, dealing with a wide range of metallurgical and engineering problems and discoveries. Abstracts of some of the papers presented on the first day of the meeting appear elsewhere in our pages (p. 502). The meeting terminated on Sept. 15 with a steamer trip on Lake Zurich. A series of tours were arranged for the meeting, in the course of which several large metal works were visited.

THE subject of the tenth autumn lecture, given by Mr. U. R. Evans on Sept. 13, before the annual autumn meeting of the Institute of Metals, was "Thin Films in Relation to Corrosion Problems". He pointed out that the thin oxide films which are responsible for the apparent stability of such metals as aluminium and stainless steel are usually too thin to give interference tints; they are invisible whilst in contact with the metallic basis, but are perfectly visible when removed from it. Although the films produced by air alone give some protection, the stability can be increased by special treatment with oxidising agents. The slightly thicker films produced on heating in air give rise to beautiful interference tints (such as the temper-colours on iron); but they tend to crack and have usually little protective value. Almost all methods of removing a film—whether an 'invisible' film or a film thick enough to produce an interference tint—depend on treatment which will dissolve the metal immediately below, thus allowing the film to peel off. For films on aluminium, nitric acid or gaseous hydrogen chloride has been used; for iron, a solution of iodine; for other metals, anodic treatment in a chloride or sulphite solution.

MOST natural oxide films, Mr. Evans explained, are not wholly impervious to ions; they contain weak points. To be useful they must be 'self-healing'; in other words, the secondary corrosion product must be precipitated so close to the weak points in the film as automatically to seal the defect. The movement of electrode potential with time provides a valuable method of observing whether, in any particular case, the weak points are healing up or are extending. A corrosion product can only be protective if produced very close to the metal. When part of the surface of an immersed metallic specimen is 'screened' from oxygen, any weak points on the screened area will tend to develop, whilst on the 'well aerated' part they will tend to heal up; foreign bodies lodging in condenser tubes often cause local attack, probably as a result of their screening action. Under conditions where metal is continually bent, or abraded, or bombarded by air bubbles, whilst in contact with a corrosive solution, the mechanical erosion will often prevent self-healing, and corrosion will then continue. Such cases cannot be explained on purely mechanical or purely chemical principles; both influences must be taken into consideration: consequently a greater collaboration between engineer and chemist is called for than has been obtained hitherto.

THERE have been many artificial ice rinks constructed in various parts of the world during the last fifty years. The essential principle of all of them is practically the same. The refrigerating plant cools a liquid which does not readily freeze; the liquid is then led through long tubes on the ice 'plate'. The tubes are placed so close together that they practically form a continuous surface of iron and any intervening gaps are caulked. A thin layer of ice about 20 mm. thick suffices, so the amount of water required is not large. Water sprinkled on the plate freezes almost at once, and the plate is undercooled to such an extent that the upper surface of the sheet of ice is kept below the melting point. The factor that governs the extent of refrigeration required is the temperature of the air above the ice. Indoor rinks are usually heated to such an extent that inactive spectators feel comfortable; the atmosphere therefore becomes unpleasant owing to its large vapour content. In the *Escher-Wyss News*, vol. 40, there is an interesting article on open-air ice rinks, with special reference to the Dolder ice-rink recently opened at Zurich. It has proved a great success; even if it rains during the night and morning, it is quite fit for skating for the rest of the day. After a shower the surface of the ice is as smooth as a mirror, as some of the rain water always freezes. The rink is situated on the heights north-east of the Dolder Park, in a sheltered position in a forest clearing, and is surrounded by fir and pine trees. At night time it is brilliantly illuminated. Owing to the crowds which frequent it, the surface of the ice wears down rapidly and it has to be freshly watered every day. The question of installing an ice factory in connexion with the rink was considered, but owing to the large number of domestic refrigerators in Zurich and the difficulty of transport it was abandoned.

AN interesting and comprehensive wood preserving exhibit is being arranged by the British Wood Preserving Association in connexion with the forthcoming meetings of the forestry subsection of the British Association. The exhibit will be staged in the Department of Botany, Imperial College of Science, Prince Consort Road, South Kensington, and will remain open during the whole meeting. A large portion of the exhibit consists of fence posts of many species of home-grown timbers collected from estates in Great Britain, which illustrate markedly the advantages of preservative treatment if timber is required to give a good life in service. Side by side with posts of timber naturally undurable, which have been made to give a life of from twenty to twenty-five years through proper treatment, are specimens of the same timbers, from the same sites, which show considerable decay in from two to six years through not having been treated. Other exhibits will show how timbers, such as Douglas fir, which do not take preservatives readily, even under pressure, can be made to absorb preservatives readily and evenly through being 'incised' before treatment. A section of the exhibit is to be devoted to the attacks of fungi and insects upon timber used in buildings, both at home and abroad.

UNDER the joint auspices of the British Association, the British Institute of Adult Education, and the Commission on Educational and Cultural Films, an exhibition is being held in South Kensington during the week of the Association's meeting, showing some mechanical aids to teaching and learning. Among other exhibits, there is to be a section for those many ingenious devices and mechanical aids which have been invented by teachers for helping their pupils to understand special points. Any teacher who is willing to lend an exhibit is asked to communicate a description of his apparatus to the honorary organiser of the Teachers' Exhibits Section, Mr. E. J. Atkinson, 4 Hawkins Crescent, Harrow, Middlesex. As it has only now been found possible to include this section, teachers interested are asked to communicate with the honorary organiser without delay.

SIR JAMES JEANS will speak under the auspices of the British Institute of Philosophy on "The Mathematical Aspect of the Universe" at University College, London, on Oct. 13, at 8.15 P.M. The public can obtain tickets (for which there is no charge) on application to the Director of Studies, University Hall, 14 Gordon Square, W.C.1.

LORD RUTHERFORD is to preside over a dinner of past and present scholars of the Royal Commission for the Exhibition of 1851, which is to be held at the Mayfair Hotel, Berkeley Square, on Monday, Sept. 28, at 7.15 (for 7.30). More than a hundred scholars have signified their intention to be present, but there are probably many others who have not yet received the notices, especially those who have left their universities abroad *en route* for the centenary meeting of the British Association. Mr. Evelyn Shaw, secretary to the Commissioners, would be glad if any research scholars of the Royal Commission who have not previously seen the announcement of the dinner, and wish to be present, would apply at once to him at No. 1 Lowther Gardens, Exhibition Road, S.W.7, for a dinner ticket, the price of which is 11*s*. 6*d*., exclusive of wines.

NEW speed records were set up at Calshot on Sept. 13, when the Schneider Trophy was won for the third consecutive time by Great Britain. Flight-Lieut. J. N. Boothman flew the course at the average speed of 340·08 miles an hour, an increase of 11·45 miles an hour on the speed reached in the last race. Later, Flight-Lieut. G. H. Stainforth made four flights along the three kilometres speed course; his average speed was about 379·05 miles per hour. Lieut. Stainforth's machine was a Vickers Supermarine Rolls-Royce, *S1596*, and the times for his four flights give the following speeds: first run, 373·85 m.p.h.; second run, 388·67 m.p.h.; third run, 369·87 m.p.h.; and fourth run, 383·81 m.p.h.

ONE of the most noteworthy of the many successful flights of the German airship *Graf Zeppelin* was the Arctic cruise which took place in the end of July this year. Dr. H. Eckener has announced through a German scientific news service some of the preliminary results of this voyage of exploration. From Leningrad the course was northward to Cape Kanin, to the east of the White Sea, and then to Franz Josef Land and 82° N. latitude. A visit was then paid to the unknown west coast of Northern or Nicholas Land and Taimir Land, after which the airship passed westward over the Yenesei mouth and the Kara Sea to Novaya Zemlya, which was traversed from north to south. The whole cruise was most successful, and was favoured by fine weather, with good visibility. The area of sea between Franz Josef Land and Northern Land is little known. The limits of Northern Land were determined and two islands discovered. Corrections were made to the charts of Franz Josef Land. A feature of the cruise was the large number of photographs and films that were taken, which should prove of great service in revising and adding to the maps.

THE physical and chemical survey of national coal resources is one of the most important tasks undertaken by the Fuel Research Board, which has an organisation now covering practically all the coal-producing areas of Great Britain. Survey Report No. 19 (London: H.M. Stationery Office, 2*s*. 6*d*. net) has been issued, containing the results of an examination of the Lower Mountain Mine Seam of the Lancashire coalfield. This seam is worked over the northern area of the coalfield, and the Survey reports on samples taken in the Burnley, Accrington, and Bacup district. The figures show the seam to contain coal with valuable properties. Its caking index is high, and typical samples have an exceptionally low sulphur content (0·4–0·6 per cent). Taken in conjunction with a low content of ash which is often highly refractory, it is clear that the coal may be used for the preparation of high-class metallurgical coke. It is the custom of the Survey to examine individually the component bands across a seam. Thus it was found that the sulphur and ash giving high average figures for the seam was at times mainly concentrated in a thin band, suggesting that an apparently indifferent coal might, by a suitable cleaning process, be made to yield a high-grade product.

WE have received the eighth number of *Brighter Biochemistry*, the illustrated journal of the Biochemical Laboratory, Cambridge (May 1931). The number is quite up to the standard of its predecessors, and the three editors may be congratulated on their production. The greater number of articles and poems are by, and about, the workers in the Sir William Dunn Institute, but other well-known names jostle those of mythical personages in its pages. A personal acquaintance with a number of the victims, as well as authors, will give the reader greater interest in the magazine: but much amusement should be obtained by those who are conversant with recent papers on different aspects of biochemistry. The price is 2*s*., which should be sent to the editors at the Sir William Dunn Institute: this is considerably cheaper than the price of most of the forms of entertainment of equivalent amusement value.

MESSRS. Baillière, Tindall, and Cox announce the early publication of Baillière's "Encyclopædia of Scientific Agriculture", in two volumes, to the production of which some eighty leading scientific workers in agriculture have contributed.

Letters to the Editor.

A Focusing Method for Producing Electron Diffraction Patterns.

IT is a well-known fact that divergent electron beams of uniform velocity can be focused by means of magnetic fields. This focusing device is used, for example, in cathode ray oscillographs. It has been found that the focusing principle can be applied successfully to experiments in which electrons are diffracted. The chief advantage, among others, lies in the considerable gain in intensity as compared with the usual methods.

The arrangement is illustrated by the diagram (Fig. 1.). Electrons are emitted from a short spiral filament or flat spiral A. A hollow metal cone B is placed at a short distance from the filament. This cone has a narrow hole (about 0·2 mm. in diameter) at its apex. The accelerating field is applied between the filament and the cone. M is the coil which produces the magnetic field and S the specimen under investigation, which is placed at such a distance from the coil that the field is practically zero. P is the photographic plate or the fluorescent screen.

The direct rays, after passing through the field coil, converge towards a point Z on the plate. The diffracted rays which emerge from the specimen describe a series of cones, the angular opening of which is determined by the individual spacing to which they belong. These cones intersect the plate in ellipses. If, however, the diameter d of the diffracting specimen is small compared with its distance D from the plate, these ellipses become very nearly circles. The region in which a series of identical cones intersects the plate has consequently a definite width, that is, the focusing is, strictly speaking, not ideal. The width is approximately $(r/D)^2d$ where r is the radius of the ring. In the accompanying photographs (Fig. 2), r/D is of the order of 1/10 for the largest ring and d about 5 mm. The width of the rings due to the imperfect focusing is therefore only about 5/100 of a millimetre.

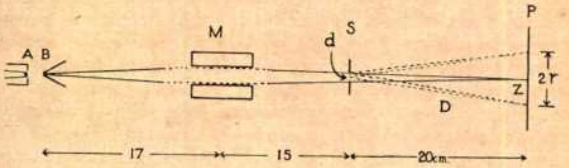

FIG. 1.

The magnetising current necessary for the focusing depends for a given apparatus essentially upon the velocity of the electrons. The adjustment is so sensitive that the current can be used directly for calibration. In the present apparatus it can be read to about 1 per cent. The determination of the electron wave-length λ is further simplified by the fact that the magnetising current is simply inversely proportional to λ over a fair range.

The use of wide beams also facilitates the otherwise rather difficult preparation of the specimens. It is, for example, feasible to use fine metal gauzes for their support. Local unevenness of the samples becomes less important owing to the averaging effect of the large area exposed.

The intensity of the diffraction patterns is high on account of the large exposed area of the sample. With a single plate Wimshurst (Wommelsdorfsche Kondensatormaschine) giving about 100 microamperes at 20-60 kv., the diffraction rings from metals, salts and paraffins can easily be observed on a fluorescent screen. The time of exposure of a photograph varies from a fraction of a second to a few seconds. The photographs accompanying this note have been obtained under these conditions. The distance specimen to plate was 20 cm.

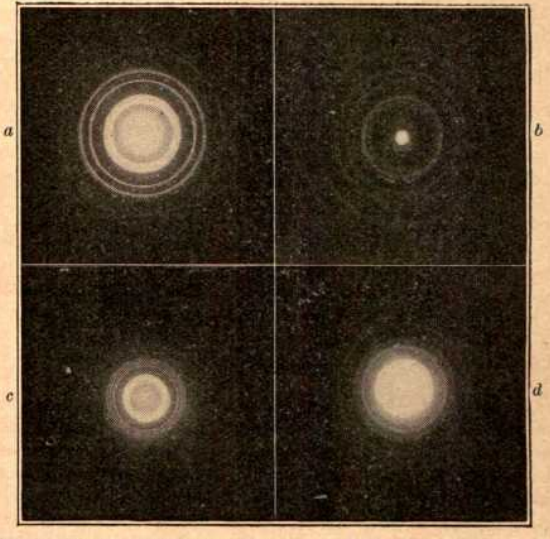

FIG. 2.—Electron diffraction patterns. *a*, Sodium chloride; *b*, gold leaf; *c*, paraffin; *d*, gold film produced by cathodic sputtering.

I wish to express my deepest gratitude to Sir William Bragg for permission to do this work in the Davy-Faraday Laboratory and to Dr. A. Muller, of the same Laboratory, for constant help and valuable advice.

Acromegaly in the Far North.

IN his letter in NATURE of Aug. 8 on the pituitristic character of Egil Skallagrimson, Prof. Seligman has brought forward a remarkable subject which made a forcible impression on myself some years ago. His opinion of the Gardariki skull confirms the existence of pituitary disorder among the viking Scandinavians, but he does not allude to the very peculiar features which distinguish Egil's case from common clinical conditions, nor to the interesting heredity which the sagas record.

Egil closely resembled his father, Skallagrim, and paternal grandfather, Kveld Ulf, in "growth, appearance, and bent of mind" (Egla S. xx., xxxi.); while the name of the latter suggests that he recalled his maternal grandfather, Ulf the Fearless, who was ancestor through a son, Hallbjorn, 'Half-Troll' (half-giant), to the equally remarkable family of Ketil Haeng, culminating in Grettir the Strong, whose bones, like Egil's, were dug up in a churchyard and admired for their astonishing size (Gretla S. lxxxiv.).

Gigantism seems to have become endemic in the

Fyrdafjord district of Sogn (Norway), where Skallagrim was able to find a dozen near his home who were "more like giants in growth and seeming than mortal men . . . all the strongest men and many shape-strong", men who, like their chief and his father, used to run 'berserk' in fits of uncontrollable rage followed by exhaustion (Egla S. xxv., xxvii.).

After the emigration to Iceland three of these giant families can be recognised by the same features reappearing in their descendants: that descended from Skallagrim, that of Giant-stead, and the descendants of Ani, among whom we may note a grandson, Steinar, who was "of all men the biggest and mighty of strength, an ugly man, crooked of growth, long-legged and short of body . . . quarrelsome and headstrong" (Egla S. lxxx.). Here again are signs resembling pituitary disorder, coupled with a morose, uncertain temper. Thorir, 'Long-chin', one of the most famous berserks, and Ofeig, 'Clumsy Foot', are other cases where characteristic pituitary features appear in a berserk family.

Egil and his father were noted for premature greying of their black hair with baldness at twenty-five. The father and grandfather of Grettir, in the line of Ofeig, 'Clumsy Foot', were also prematurely grey. The precocity, both mental and physical, of Egil and his brother may be associated with this premature senility, and possibly indicate a correlated excess of either adrenal or pineal function. Skallagrim had several children who died young, but there is no suggestion that they suffered from a total premature senility, and in such case the father and Egil the surviving son would scarcely live to the ages of 88 and 81 respectively, or perform astonishing feats of strength on the day of death.

Grettir, far from being precocious was distinctly backward, and seems unexpectedly feeble in the development of genitalia (Gretla S. xiv., lxxv.): possibly in his case pituitary disorder passed into a stage of hypo-function, but he was in full vigour when killed at 35. Although mentally very alert and a clever poet like Egil and Skallagrim, Grettir like his father was noted for laziness, which also suggests hypo-function. On the other hand, the Egil family were unusually brisk; but Thorbjorg the Fat, a granddaughter of Egil, may have developed pituitary hypo-function. Egil had also, and Grettir was credited with a son who died at 17, after promising to develop into something altogether extraordinary (Gretla S. lxvii.)

The tendency to berserk (*hamask*), so obviously resembling the running *amok* of Malays, was closely interwoven with "shape-changing" or being "shape strong" (*hamrammr*, vide T. R. Eddison, 1930, "Egil's Saga", notes, p. 245 ff.; and Du Chaillu, 1889, "Viking Age", ii. p. 425). The latter may broadly be regarded as peculiar behaviour in the dusk, such as sleepiness and surliness (Kveld Ulf), berserk fits (Skallagrim), mad drinking fits (Egil), dusk prowling, supposedly in animal shape (Storolf Haengson), terror of the dark (Grettir). We may imagine that evening terrors would provoke an adrenal release which might become translated, in those with constitutional adrenal excess, into a fit of berserk rage. Berserk fits, being involuntary, may also be compared with the 'uncinate' epileptiform seizures of pituitary hypertrophy, and there seems to be a strong hysterical element, because the subject was believed to be impossible to wound, which may mean that he was insensible to pain and did not bleed from non-arterial traumata.

As regards heredity, I have traced 52 male and 19 female descendants of Ulf the Fearless in 12 generations. Seventeen of the males are recorded as peculiar in one or more of the above ways, 6 others probably were so, but details are not available in the sagas at my hand, and of these 4 males evidently transmitted the heritage: 4 males transmitted without being noticed as unusual themselves. Females naturally have attracted less attention, but 3 of the 19 seem to have been unusual and 8 transmitted. Skallagrim and Grettir were each the offspring of berserk families on both sides—among 14 members of the associated families, 7 seem to have been peculiar; while the two other berserk families from Fyrdafjord referred to above include 7 peculiar among 9 individuals. In brief, half, of both sexes, may be believed to have had a peculiar hereditary constitution; and the condition seems not to be sex-linked. These details are drawn from the well-known sagas of Egil, Grettir, Laxdale, Burnt Njal, and the Norse Kings: lack of space makes publication of the genealogical table inadvisable, while it may yet be improved by reference to the sagas of Ketil Haeng and others not yet translated. It is certain that descendants of Ulf the Fearless settled in Greenland, because, soon after its discovery, fourteen ships reached that land from Borgafjord of Skallagrim's settling, and Breidafjord the home of Grettir's mother, through whom he derived from Ulf: it is therefore quite possible that the Gardariki skulls include some of Ulf's descendants.

The description of the unusually tall Grettir as "a handsome man . . . with a face rather broad and short, red-haired and somewhat freckled" (Gretla S. xiv.), places him at once as that well-known German-resembling Caledonian type which attracted the attention of Tacitus; it also suggests the much more ancient Cro-Magnon with dysharmonic face, a conspicuously giant type.

On the other hand, the Egil family, with its black hair, great height, thick skull, prognathism, precocity, and fits of rage, is curiously parallel to the tall negroid in everything except indolence, which was certainly displayed on the Grettir side, and pigmentation of the skin. *Hamrammr* may even be compared with the 'Leopard Society' prowling of West Africa. This parallel is interesting, because rock-tracings at Tanum in South Sweden introduce us to sea raiders and settlers who were familiar with the leopard, the camel, the ostrich, and the turtle, as pointed out by Du Chaillu ("Viking Age", ii. p. 124). Some are represented of immense size, many are prognathous—with a suggestion of the acromegalic chin—some have unusually long legs and short bodies like Steinar, several are remarkably fat; often pictured fighting with vigour, they might well represent ancestors of Egil. Also the Fomorians, supernatural giants, who exactly parallel the Scandinavian Trolls in Irish tradition and played the part of vikings in their earliest history, were explained as "sea-raiders from Africa" by the medieval scholarship in Keating's well-known "History of Ireland". As a hypothesis, the tall and fair Scandinavian, or even taller red Caledonian, raiding up and down the Atlantic coasts in very early days, might conceivably contact with the tall negroids of Jaloff, and thus acquire with captured women the seeds of a black-haired stock unbalanced in many ways and marked by excessive height, such as that producing Egil Skallagrimson.

5 Little Cloisters,
Westminster Abbey, S.W.1.

APART from the high scientific value of Prof. Hogben's comments,[1] there is an immediate practical application.

Cases of infantilism—not the most severe—due to hypo-function of the anterior portion of the pituitary, though not very uncommon, are extremely difficult to treat, since no harmless reliable extract of the gland suitable for hypodermic injection is yet on the market and authorities are still doubtful as to how far anterior pituitary extract is absorbed when given by the mouth. If, as suggested, the gland is stimulated by light, then such individuals should profit by a stay during the darker part of our English year at higher altitudes, in areas with more sunlight than we get in this country. It happens that for some years I have been interested in a case of moderate infantilism due to anterior pituitary deficiency, and the improvement during a year in Switzerland (beginning in the autumn) at a height of about 3000 feet, with bright days and a good deal of snow in winter, greatly exceeded the progress made in any previous year in a boarding-school in the south of England, the hours of work indoors not being very different. That the psychic conditions were more favourable in Switzerland should, however, be taken into consideration.

An Oxidisable 'Active Nitrogen'.

IN the earlier part of this century it was often the practice to decolorise flour by exposing it to dilute nitrous gases obtained by sparking air, and in studies made by Leetham (1903) and Cramp and Hoyle (1907) it was found that the bleaching properties of the gases thus prepared were much enhanced if the air were ozonised before it entered the small H.T. arcs in which the nitrogen oxides were formed; this effect could be traced to an increase in the yield of nitrogen peroxide when ozone was present in the air supply.

In 1912 Lowry investigated the phenomenon quantitatively by photographing the nitrogen peroxide absorption spectrum in a column of gas 64 ft. long, this great length being rendered necessary by the extensive dilution of the substance being measured (1 : 3000 to 1 : 1000), and found that the effect could also be observed when the air was treated with ozone *after* being sparked; from this and other evidence of less importance he concluded that an unstable modification of nitrogen, which can be oxidised by ozone but not by oxygen, is produced in the main discharge. As the Rayleigh active nitrogen does not react either with oxygen or with ozone we have made a further examination of Lowry's very interesting claims, but using a different, and, we believe, an entirely new, technique of measurement of the nitrogen peroxide.

Our method depends upon the fact that the spectral region wherever nitrogen peroxide absorbs most strongly is close to that at which a vacuum potassium photocell is most sensitive (namely, the blue-green), and we have found that when intensity of light transmitted (calculated from the photoelectric current) is plotted against concentration of absorbent gas, the Beer-Lambert law holds between 0·01 and 3·25 per cent NO_2, the range wherein we have worked. It is thus possible to effect practically instantaneous determinations of nitrogen peroxide, and by suitable choice of (*a*) length of gas column, and (*b*) accuracy of measurement of photoelectric current, the method can be made to give results much more exact than those obtainable by ordinary spectroscopic means; in our work, where concentrations of 1 : 3500 to 1 : 1000 have been encountered, we have used a column only 8 inches long but with a 6 ft. column, 1 part of NO_2 in 75,000 of air may easily be determined.

We have made an extended search, using both pure nitrogen and nitrogen-oxygen mixtures over a wide range of experimental conditions, for any oxidisable modification of nitrogen or for any nitrogen oxide which may react only with ozone and not with oxygen, but have obtained no evidence for any such substance, although we have confirmed the earlier findings as to the increase in NO_2 yields when the air is ozonised before or treated with ozone after it is sparked; this last effect may, however, be observed only when the time which elapses between the gas leaving the spark and entering the measuring tubes is very small.

The explanation of the results obtained by earlier investigators would, therefore, appear as follows. The primary product of the spark in air is nitric oxide, which can change to nitrogen peroxide either by the slow termolecular reaction with oxygen or by the rapid bimolecular reaction with ozone. We have calculated, from an application of Bodenstein's data (1919) upon the kinetics of the former reaction to the experimental data given by Lowry, that under his usual conditions the NO would be less than half oxidised before it reached the downstream end of his 64 ft. trunk, whereas with ozone present the oxidation would be complete even before the gas entered this tube.

This calculation has been entirely verified in experiments in which two absorption tubes have been used, one immediately below the discharge and the other some distance from it; the concentration of NO_2 measured in the first is much less, at high flow speeds, than in the second, whereas, as the gas velocity is gradually reduced the difference becomes progressively smaller and finally disappears, an effect which is paralleled by Lowry's observation that the effects of ozonising either before or after sparking are negligible at small flow speeds.

We would point out that Lowry several times suggests that the slow oxidation of nitric oxide by oxygen may account for his observations, but, possibly owing to there having been no accurate data available upon the kinetics of the reaction at the time of his investigations, rejects this explanation in favour of that already mentioned: hence, while we can confirm his experiments, we cannot, in the light of present knowledge, accept his theory.

A full account of these experiments will shortly be published.

Cytology of *Anchusa* and its Relation to the Taxonomy of the Genus.

Anchusa myosotidiflora was placed in the genus *Anchusa* by Lehmann [1] in 1818 after being originally described as *Myosotis macrophylla* by Marschall [2] in 1808. In 1851, C. Stevens [3] assigned it to the newly described genus *Brunnera*, calling it *Brunnera myosotidiflora*. This splitting of the genus, however, was not accepted until the almost simultaneous publications of Ivan M. Johnston [4] and O. Stapf [5] appeared, the species being regarded as members of *Anchusa* by M. Gürke [6] and others. Johnston concluded that *A. myosotidiflora* with its variety *grandiflora* and *A. neglecta*, because of their "peculiar nutlets, leafy and ranker habit, and different inflorescence", fully deserved the position given them by Stevens. He accordingly retained them in the genus *Brunnera* and by following the law of priority as *B. macrophylla*, *B. sibirica*, and *B. orientalis*.

Caryolopha sempervirens (L.) Fischer and Trautvetter[7] (1837), like *Brunnera*, was also referred in more recent works to the closely related genus, *Anchusa*, but on morphological grounds Johnston considered it also merited recognition as generically distinct from *Anchusa*.

A tabular comparison of Johnston's arrangement with that of Gurke, with a summary of my own cytological observations (Fig. 1), is given below.

Gurke's Classification.	2n Chromosome Number.	Chromosome Types Classified according to Position of Point of Attachment.			Chromosome Length in Microns.		Johnston's Classification.
		Sub-terminal.	Median.	Sub-median.	Shortest.	Longest.	
Anchusa Barrelieri	16	2	4	10	4 2	6 1	*Anchusa Barrelieri*
,, *ochroleuca* seedling	24	3	6	15	5 5	8 0	,, *ochroleuca* seedling
,, *italica* var. 'Pride of Dover'	32	4	6	22	4 7	8 5	,, *italica* var. 'Pride of Dover'
,, *officinalis*	16	2	6	8	5 9	8 5	,, *officinalis*
,, *hybrida*	16	2	6	8	5·2	7 8	,, *hybrida*
,, *sempervirens*	22	4	6	12	1 8	3·8	*Caryolopha sempervirens*
,, *myosotidiflora*	12	4	2	6	1·4	3 0	*Brunnera macrophylla*

It is apparent that Johnston's changes in classification are fully substantiated by the microscopical observations, for both *Brunnera* and *Caryolopha* differ markedly from each other and from *Anchusa* in size, type and number of chromosomes. Nevertheless, while recognising that collectively these differences justify the generic changes, there is to be seen a definite similarity between certain chromosomes of all three genera which may possibly indicate the moderately close relationship which Johnston assumes exists between them.

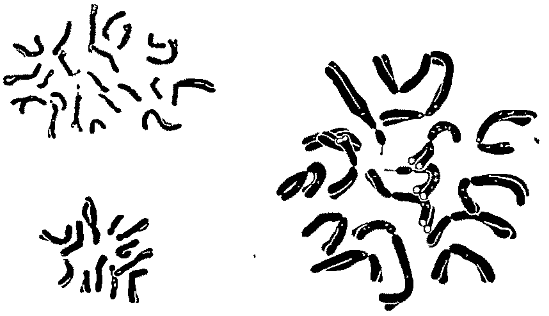

FIG 1.—Chromosomes of *Caryolopha sempervirens* (top left hand); *Brunnera macrophylla* (bottom left hand); *Anchusa officinalis* (right).

In a less abbreviated account to be published shortly, it is hoped to indicate more fully the value of cytology as a corroborant of herbarium methods in the classification of plants.

Thrips tabaci as a Vector of Plant Virus Disease.

IN NATURE of June 6, Dr. Kenneth Smith reports finding *Thrips tabaci* Lind. to be a vector of tomato spotted wilt in England. Since recent Australian work on the transmission of this disease has not yet been published, the following particulars may also be of interest:

The first record of successful insect transmission of tomato spotted wilt was made by Pittman,[1] who described three experiments with thrips; the insects used in the last of these experiments were identified by an entomologist as *Thrips tabaci*. Later, Samuel, Bald, and Pittman published a bulletin,[2] in which the main vector of the disease in South Australia was claimed to be the thrips *Frankliniella insularis* Franklin. In this bulletin a number of experiments with *Thrips tabaci* were recorded which proved negative, but the possibility that *Thrips tabaci* might act as a vector was not yet excluded. This was because transmission, even with *Frankliniella insularis*, was often so irregular that it was felt that some unknown factor influencing transmission had not been discovered. Another fact which indicated that *Frankliniella insularis* was not the only vector was that spotted wilt was a serious disease in Victoria, although *Frankliniella insularis* was extremely rare in Victoria.

In a bulletin now in the press, further work on transmission with *Frankliniella insularis* is described, in which it was found that when adult thrips were fed on a diseased plant and then transferred to healthy plants the disease was never transmitted. For successful transmission to occur, it proved to be essential that the thrips should have fed on the diseased plant in the *larval* stage. No analogous case with other insect vectors of virus diseases appears to have been described yet. (One of the writers, G. S., however, was much interested to find, on passing through Honolulu recently, that Dr. M. B. Linford, of the Hawaiian Pineapple Growers' Experiment Station, had discovered that *Thrips tabaci*, the insect vector of the yellow-spot disease of pineapple, was also unable to transmit the disease unless it had fed on a diseased plant during its larval stage.)

With this additional information of transmission, and also the fact that the incubation period of the virus in the thrips (*Frankliniella*) was found to be between five and seven days, the experiments with *Thrips tabaci* are being repeated. Already this species has been found to act as a vector of spotted wilt, as originally claimed by Pittman, and as now verified independently from England by Dr. Kenneth Smith. It is not yet known whether this, or possibly still another species of thrips, is the vector of the disease in Victoria. Several facts, however, suggest that in South Australia *Frankliniella insularis* is a more 'efficient' vector of the disease than *Thrips tabaci*.

Dr. Smith's observations on dahlia plants infected with spotted wilt are also interesting. In our forthcoming bulletin, besides thirty species of *Solanaceæ*, three species in the *Compositæ* and one each in the *Papaveraceæ* and *Tropæolaceæ* are proved to be hosts for the spotted wilt virus.

Lines of Large Frequency Shift in the Raman Spectra of Crystals.

Prof. F. Rasetti[1] has described lines in the Raman spectrum of fluorite and calcite, which show a remarkably large shift of about 7000 cm⁻¹. Owing to the theoretical importance of this fact, which would indicate the co-operation of electronic transitions of considerable energy in the Raman spectra, I wish to point out that these lines can be explained as lines of the phosphorescence of gadolinium. It is a well-known fact that natural fluorite nearly always contains rare earths. These earths, when excited by ultra-violet light or cathode rays, show a phosphorescence having a spectrum of very sharp lines. The spectrum of fluorite was examined by G. Urbain.[2] The following table shows that the observed lines coincide with the lines of phosphorescence of gadolinium.

$\Delta\nu$ from Hg λ2537.	Observed lines. λ	Lines of gadolinium, after Urbain. λ
7256	3109	3108
7273	3110	3110
7285	3112	3113
7298	3113	3115

The agreement is as good as the limit of error in the exact measurement of the lines of phosphorescence will allow. In addition, Urbain observed other lines between 3118 A. and 3147 A. That these lines were not observed in the Raman spectrum is easily understood. These lines coincide partly with the strong lines of mercury in this region, and further, Urbain showed that the lines between 3147 A. and 3132 A. disappear when the amount of gadolinium in the fluorite becomes very small. Conversely we can conclude that the material examined by Prof. Rasetti contained only a very small quantity of gadolinium.

An analysis of the spectrum of calcite is not possible, since the spectrum of phosphorescence of gadolinium in calcite has not yet been examined. The known spectrum in calcium oxide shows also in the spectral region under consideration the main lines of gadolinium. Hence in the examination of materials which are likely to show a phosphorescence spectrum of sharp lines, the appearance of such lines, as well as the lines of the Raman spectrum, is, if they are excited with ultra-violet light, always possible.

It can also be seen from the above, that similar lines of large frequency shift are not recognisable in the examination of other materials, since they most probably contain no rare earths.

The Fine Structure of Spectral Lines of Light Scattered by Liquids.

Gross[1] has investigated by means of an echelon grating the fine structure of spectral lines scattered by liquids, and has found that in addition to the lines scattered without change of wave-length there appear new lines symmetrically situated relatively to the primary ones. The number of those new lines depends from the substance investigated, and the distance between them depends upon the angle formed by the incident and the dispersed rays.

Similar investigations were carried out by Vacher.[2] He used for that purpose a Fabry Perot interferometer. His observations, however, do not confirm Gross's results. Though he found that the primary line is widened by increasing the angle between the incident beam and the direction of observation, yet he states that this widening takes place only towards the long wave-length. Also, he did not observe the appearance of single lines.

The discordance between the results mentioned above induced me to undertake a similar investigation, using a different experimental arrangement. I put the vessel with the liquid investigated inside the mercury lamp, which had the form of a ring (the detailed description of the apparatus will be given in a paper which will be published in *Bull. de l'Acad. Pol.*). A current of 4½ amp. passed through the lamp burning at 110 v. The scattered light after passing through a monochromator fell on a Lummer-Gehrcke plate. I used in my experiments two different quartz plates of thicknesses of 3·92 mm. and 6·888 mm. and lengths of 13 cm. and 20 cm. respectively. In the case of benzene there does not appear in the scattered light any new line, though the components observed by Gross were of the same intensity as the primary component. Taking in consideration Gross's data, those lines should appear half-way between the neighbouring orders of the primary line. The spectra of the scattered light in both cases, benzene and white paper, differ only by the continuous background and by a slight widening of the lines which appears in the case of benzene. I obtained similar results with water.

The same experiments were undertaken with a different arrangement of apparatus; I irradiated the liquid at a definite angle (90°). In this case also the spectrum does not alter in any noteworthy way.

Since Vacher and I are not able to confirm the phenomenon observed by Gross by means of other interferometric apparatus (Fabry Perot interferometer and Lummer-Gehrcke plate), hence a more accurate investigation of that problem, and the explanation of the difficulties involved, would be desirable.

Vitamin A and the Antimony Chloride Reaction.

For the determination of vitamin A by means of the reaction of Carr and Price, the blue colour of the mixture is estimated with the Lovibond tintometer. If analysed by the spectroscope, the blue mixture shows two absorption-bands at 572$\mu\mu$ and 610$\mu\mu$ respectively (Morton). The blue colour depends only on the intensity of the 610 band.

Recently Morton and Heilbron have announced that the strength of different vitamin A preparations corresponds better with the extinction of the mixture in the 572$\mu\mu$ region than in the 610$\mu\mu$ region.

We can confirm this by the following facts: By treating a vitamin A preparation from saponified cod liver oil or saponified extract of cow's liver with some drops of furan, methylfuran, pyrrol, indol, or skatol (all substances of related chemical structure) and then adding antimony chloride, the mixture turns purple instead of blue, and in the spectroscope the 610$\mu\mu$ band is no longer seen, while the 572$\mu\mu$ band remains unaltered. The physiological activity is unimpaired and the preparation (without antimony chloride) shows the 328$\mu\mu$ band just as the original substance did.

It is known that liver may contain indol-like substances and so it can be understood that in some vitamin A preparations the 572$\mu\mu$ band is the stronger and in others the 610$\mu\mu$ band is the stronger. In fact, we have obtained saponified vitamin A preparations in which the two bands were of equal strength and others in which either the 610$\mu\mu$ band or the 572$\mu\mu$ band was the more intense.

Effect of Light on the Surface Tension of Boys's Soap Solutions.

While investigating the phenomenon of the surface tension of different dilutions of Boys's soap solutions (2·5 per cent sodium oleate and 25 per cent glycerine in water) I found that, whenever the solution was exposed to light, there was an abrupt but small fall of surface tension of the solution; but when the solution was kept in a cool, dark room, this abrupt change was not noticed during the experiment, if all the other conditions remain the same.[1]

In 1924, Du Nouy[2] found that the surface tension of colloidal solutions is not constant, but decreases rapidly as a function of time, and concluded that this phenomenon is due to the adsorption of the molecules in suspension, in the surface layers, as a function of time.

I have found now, by two different methods, namely (1) the surface tension balance method[3] and (2) the weighing method,[4] that the decrease in surface tension is a function of the time for which the solution is exposed to light, and not a mere function of the time as found by Du Nouy. The dark time—that is, the time for which the soap solutions are kept in a cool, dark room—has almost no effect on the surface tension of soap solutions. A possible reason for this is a chemical action, not adsorption in the surface layers alone.

The detailed study of the investigation, with observations, curves, and discussion, will soon appear in the *Indian Journal of Physics*, Calcutta.

Inheritance of Melanism in Moths.

In 1926, Prof. J. W. Heslop Harrison and Dr. F. C. Garrett published an account of experiments in which the moth *Selenia bilunaria* was fed upon hawthorn foliage which had been artificially contaminated with salts of lead and manganese respectively. In the second generation of moths fed upon the treated material, melanic forms appeared; and the melanism afterwards was inherited on Mendelian lines. No melanics appeared in the control moths fed upon untreated foliage.

So important are these results as regards the origin of mutations that a repetition of the experiments was begun at the John Innes Horticultural Institution in 1927. Three families from three different localities have been reared, one for five and two for six inbred generations. After two generations fed upon untreated foliage had been raised, in order to ascertain that the material was genetically pure, portions of each family were fed upon foliage treated with lead and manganese respectively, a control portion being also retained on untreated foliage. In all, 1231 control, 1472 lead treated, and 283 manganese treated moths have been reared, and no signs of melanism have appeared in any individual. Analysis showed that the lead, at any rate, was present in the moths of the final generation reared.

A detailed account of the experiments is being prepared for publication; the results, being negative, lead to no immediate conclusions on the hypotheses that had been advanced to account for the results of Prof. Harrison and Dr. Garrett.

The Structure of the Spectrum Se III.

The analysis of the spectra Se IV and Se V has been reported by us in a previous paper.[1] The experimental data described there have led further to the identification of a system of energy-levels characteristic of the spectrum of doubly-ionised selenium. Combinations between the deepest terms $4s^2 4p^2$, ${}^3P$, ${}^1D$ and the terms $4s^2 4p5s$ ${}^3P$, ${}^1P$ have been established by comparison with the spectra of Ge I and As II (unpublished data by K. R. Rao). About two hundred lines belonging to the spectrum have entered into the scheme. The $4s^2 4p^2$ term-differences are ${}^3P_0 - {}^3P_1 = 1740$, ${}^3P_1 - {}^3P_2 = 2196$, ${}^3P_2 - {}^1D_2 = 9095$, the $4s^2 4p5s$ differences are ${}^3P_0 - {}^3P_1 = 504$, ${}^3P_1 - {}^3P_2 = 3610$, ${}^3P_2 - {}^1P_0 = 1265$, and $4s^2 4p^2$ ${}^3P_2 - 4s^2 4p5s$ ${}^3P_2 = \nu 126454$ ($\lambda = 790{\cdot}80$).

The above work was done partly at the Imperial College, London, and partly at the Physical Laboratory, Uppsala. A full report will be published later.

Group-Capt. Martin Flack.

In my obituary notice of the late Group-Capt. Martin Flack, I mentioned the fact that, "beginning research with Sir Arthur Keith, he discovered anatomically the sinu-auricular node". These words perhaps do not express fully enough the debt which Martin Flack owed to Sir Arthur, who had been searching for such a structure. He put Flack on to the examination of the heart of a mole, which first gave clear evidence of a structure of which he (Sir Arthur) had found some evidences in the human hearts sent to him for examination by Sir James Mackenzie. Flack completed the discovery by experimental evidence, in the case of hearts of living animals.

Sept. 11.

Radioactivity and Earth Movements.

In a notice of my Glasgow lecture on this subject (Nature, Sept. 5, 1931, p. 419) occurs the passage: "Amongst other instructive conclusions are that 'we may regard the Pacific crust as being like that of the continents' (p. 570)". As I have already received several invitations to justify this alleged "conclusion", I wish to point out that what I actually wrote was: "we may therefore regard the Pacific crust as being like that of the continents, but with gabbro passing down into amphibolite in place of the sialic upper layer".

Arthur Holmes.

Durham, Sept. 12.

Research Items.

Hawaiian Temples.—In the course of a study of the archæology of Kauai Island, Hawaii (*Bull.* No. 80, Bernice P. Bishop Museum), Dr. Windell Clark Bennett describes the various types of *heiaus* (temples), of which there are traces, and discusses their uses and affinities. To-day only their foundations survive. Temple forms are influenced by two factors. Many old temples were remodelled by later chiefs; and the temple architect was a priest whose business it was to study the forms of old *heiaus* and design new ones, incorporating features which seemed to him the cause of the success of important *heiaus*. A great confusion of forms and features was the result. The principal types in both small and large *heiaus* are those (1) with open platforms, (2) walled enclosures, (3) terraced platforms; each of these in the group of larger *heiaus* having several subdivisions. In function the *heiaus* fall into five general classes: (1) The sacrificial *heiau*, called by various names, but chiefly *luakini* and *pookanaka*. (2) The agricultural *heiau*, for which one of the commonest names was *heiau hoouluulu*. Its purpose was to induce rain, increase the crops, and fulfil any other purpose useful to agriculture. (3) Fishing shrines, *hoa*, located along the shore and used in sacrificing to the fish god in order to increase the catch of fish. (4) The *pohaka o kane* or family *heiau*, for private prayer or worship. (5) Miscellaneous *heiaus*, including a great variety of *heiaus* built by lesser chiefs and priests for such purposes as circumcision, aid in child-birth, impelling love, paying debts, surf riding, hula dancing, and tapa making. To-day the purpose of the *heiaus* is little known and the information given is likely to be faulty. There seems to be no connexion between the functional and descriptive classifications.

Malaria in South Africa.—An important survey of the distribution and conditions of spread and of control of malaria in the Transvaal and Natal has been carried out by Prof. N. H. Swellengrebel ("Report on Investigation into Malaria in the Union of South Africa, 1930–31". Union of S. Africa: Dep. Pub. Health, Pretoria, 1931). Of some twenty species of anopheline mosquitoes met with in these two countries, only two, *A. costalis* and *A. funestus*, are of practical importance as vectors of malaria, because they alone enter into such close contact with man that they become infected; this fact much simplifies anti-mosquito, and particularly anti-larval, measures. Interesting details are given of the distribution of various species of anopheline larvæ that may occur in the collections of water met with on an average farm. The prophylactic use of quinine and screening from mosquitoes are found definitely to reduce the incidence of malaria, judged by the 'spleen rate'. Thus the spleen rate among children was 88 per cent in unscreened farms and 44 per cent in screened ones, even though these measures were far from perfect. Recommendations are made for the control of malaria, and include the formation of an administrative control unit and a research field station, instruction of school teachers and of future farmers' wives in the principles of hygiene and anti-malarial measures, promotion of the sale of quinine by the Government, and a system of medical examination of recruited labour before acceptance, so that malaria carriers may be detected and excluded.

Starch Digestion in Silkworms.—It is widely believed that the nutrition of herbivorous insects depends chiefly upon the carbohydrates, starch especially, of their food substances; and in regard to the silkworm it has even been recommended that the nutritive values of mulberry leaves might be determined by the iodine reactions of the leaves. Osamu Shinoda shows that in one race of silkworm ("Hasegawa-Shimpaku") starch is not digested at all (*Annot. Zool. Japon.*, vol. 13, p. 117; 1931). Since the sugar content of the leaves is too low to sustain the life of the larva, whence does it synthesise the carbohydrates? Apparently from proteins, in the presence of desamidase, which is shown to exist in the blood of the fifth instar larvæ experimented with. Another significant discovery was that the wall of the hind-gut was impermeable to glucose, and this leads the author to suggest that the symbiont hypothesis of hind-intestinal organisms in various xylophagous insects (for example, the protozoa of termites, or bacteria of lamellicorn beetle larvæ) requires many more confirmatory experiments.

The Permeability of Protoplasm to Water.—The rate of contraction of the protoplast in a cylindrical plant cell, such as the filament of *Spirogyra* provides during the process of plasmolysis, proceeds so regularly and symmetrically that the volume alterations of the protoplast with time can readily be measured. The velocities thus obtained must either be determined by the rate at which the external solution is penetrating the cell wall, or by the rate at which the solvent, water, is leaving the protoplast. In *Die Naturwissenschaften*, July 24, 1931, Bruno Huber shows that good grounds exist for regarding the velocity of such volume changes as a measure of the permeability of the protoplasm to water. When such measurements are extended over a wide range of biological material, it is evident that the living protoplast has a characteristic water permeability, very different in different objects, in different species, or even in different tissues of the same plant. In a study of the cells of the stem hypodermis of *Majanthemum bifolium*, it appeared that the permeability of the protoplast for water was 10,000 times as high as for cane sugar, 600 times as for potassium nitrate, and 120-140 times as for urea. These data supply interesting quantitative evidence for the 'semi-permeability' of protoplasm in which, as Lillie expressed it (*Amer. Jour. of Physiol.*, 45, p. 406; 1918), "a high degree of semi-permeability . . . appears to require a high degree of impermeability to water".

Genetics of Japanese Morning Glory.—The genetics of the Japanese Morning Glory, *Pharbitis Nil*, has been studied entirely in Japan, during the last twenty years. The species shows much variation in flower-colour and pattern. In a paper by Yoshitaka Imai (*Jour. of Genetics*, vol. 24, No. 2) twenty-one genes affecting flower-colour have been studied. There are three different types of white, as well as purple, magenta, duskish tinged, speckled, rayed, flecked, etc. Flecked and duskish are two mutable genes. The former shows much variation and may give rise to self-coloured bud-sports. Normal plants derived by seed from the normal part of a mosaic flecked plant are in part homozygous normal and in part heterozygous for flecked. Some 'fringed' flowers also arise, which are found to be periclinal chimæras. Duskish gives about one per cent of mutations to the normal blue, and also certain variegated types which vary widely.

Carboniferous Bellerophons.—A memoir by Dr. J. Weir on the "British and Belgian Carboniferous Bellerophontidæ" (*Trans. Roy. Soc.*, Edinburgh, 56, 1931, pp. 767-861, pls. i.-ix.) completes the history of this group of Palæozoic gasteropods in the British area. The forms from the Ordovician and Silurian have already been described by Cowper Reed, and those from the Devonian by G. F. Whidborne in monographs published by the Palæontographical Society. Dr. Weir recognises 78 species and varieties of Bellerophontids in the Carboniferous belonging to 7 genera: *Bellerophon, Waagenella, Bucaniopsis, Patellostium, Tropidocyclus, Zonidiscus*, and *Euphemus*.

Quaternary Ice Margins (North Sea).—Prof. J. K. Charlesworth has published and described a valuable map of north-west Europe, showing the successive positions of the Quaternary ice-margins in the region of the North Sea (*Proc. Roy. Irish Acad.*, **40**, B (4), 1931, pp. 67-83). It is concluded that the Elster and Saale glaciations of Germany and Holland correspond to the older drifts of the British Isles. At the period of the Saale glaciation the ice-sheets were united and their margin over the North Sea cusp-shaped. The Newer Drift of the British Isles is equivalent to the Brandenburg stage of the Continent (or possibly to the Warthe stage). At this time the British ice was separate from the Norwegian ice and formed a piedmont mass over the western part of the North Sea. The Highland glaciation is of the same age as the Finiglacial stage of Fennoscandia; both were local in their distribution and bordered by the late-glacial sea. The new reconstruction, the first to be attempted by a British geologist, corrects certain errors in two of a series of maps recently published by Antevs to show the extent and distribution of the Quaternary ice-sheets in different parts of the world (*Bull. Geol. Soc. Am.*, **40**, 1930, pp. 631-720).

Curvature of Island and Mountain Arcs.—In Nature for Nov. 15, 1930 (vol. 126, p. 787), an account is given of Dr. N. Kumagai's investigation of the form of the Japan islands arc. Prof. T. Terada has recently continued the subject, taking other insular arcs and several mountain ranges (*Earthq. Res. Inst. Bull.*, vol. 9, pp. 144-150; 1931). The island arcs belong to four groups, those of the Pacific Ocean, the West Indies, the Atlantic and Indian Oceans. The results are plotted by taking the latitude of the middle point of the arc as abscissa and the radius of curvature of the arc as ordinate. The diagram is divided into three regions by two straight lines drawn from the origin. The Pacific and West Indian groups lie in the middle region, a result that is of some interest, as the West Indies are usually cited as belonging morphologically to the same type as the Pacific islands. The Atlantic and Mediterranean groups lie in the sector of smallest radius of curvature, and the Indian Ocean group in that of largest radius. In the middle section, and to some extent in the others also, the radius of curvature increases with the latitude. A second diagram shows the corresponding relations for mountain-ranges, and it is worthy of notice that the European mountain arcs fall in the same zone as the Atlantic and Mediterranean island arcs, while the Asiatic mountain-ranges lie, like the Pacific islands arcs, in the middle zone.

Electrification of Coal Dust.—When, in ventilating a coal mine, air containing small quantities of coal dust in suspension is drawn or forced through metal ducts, it is found that the whirling action of the air on the dust is capable of electrifying the dust, and that the electric charges generated are communicated to the metal ducts. If these ducts are highly insulated, they may be raised in electrical potential sufficiently to cause sparks to pass from the ducts to surrounding objects. A research carried out by Messrs. S. C. Blacktin and H. Robinson, of the Safety in Mines Research Board, and issued as Paper No. 71 (London: H.M. Stationery Office, 6*d*.), shows that in order to get such sparks as would be sufficient to cause an explosion of firedamp in a mine, the insulation of the metal ducts has to be so good that under actual mining conditions it would only exceptionally be reached, and the chance of an explosion being produced by this cause is correspondingly small.

Generalised Thermodynamics.—Many attempts to derive the second law of thermodynamics from statistical theories have been made, but particular interest is attached to that given by Prof. G. N. Lewis in the July issue of the *Journal of the American Chemical Society*. The method differs considerably from those of classical thermodynamics and of statistical mechanics, and from a single postulate it is shown that the laws of thermodynamics and the laws of fluctuations are derivable as a generalised thermodynamics. The partition of a quantity x between two (or more) independent systems is made to depend on what are defined as specific probabilities, the ratio of which, for any two partitions, is postulated as dependent solely on the nature of the two systems and on their respective contents. The definition of temperature, entropy and its relation to fluctuations, and thence the general equations of thermodynamics, follow mathematically. Prof. Lewis considers that his postulate constitutes the first really valid statement of the second law of thermodynamics, and his deductions are certainly very interesting and rigorous.

Prediction of Isotopes.—The *Journal of the American Chemical Society* for August contains two papers dealing with the above subject. In the first, by H. L. Johnston, an arrangement which is a kind of periodic table is used, the atoms being arranged in order of isotopic mass numbers. The atoms are first arranged in four main types: the $4N$ type, with atomic weights exactly divisible by four, and regarded as composed of N alpha-particles; the $4N+1$ type, containing one free proton; and the $4N+2$ and $4N+3$ types, containing two and three free protons. A further classification is carried out, based on the number of 'free' electrons in respective nuclei, the numbers at the heads of columns representing nuclear electrons in excess of $2N$, which may be arbitrarily taken as nuclear electrons outside α-particles. Atoms experimentally observed and reported are shown, and possible but hitherto undiscovered atoms are indicated. The latter include Sr^{84}, Zr^{88}, Pd^{104}, Cd^{108}, Te^{120}, A^{38}, Ca^{42}, etc. Aston has directed attention to an isobaric triplet of mass 96, and the table predicts triplets of masses 77 and 124. Certain regularities in the table are emphasised as possibly having significance with respect to structural relationships within the nuclei. The second paper, by H. C. Urey, uses the plot of numbers of nuclear protons and electrons as co-ordinates, as proposed by Barton. The known nuclei lie on this diagram between two lines of slopes 2 and 1·61, there being well-defined clusters, each possessing an approximate centre of symmetry. The pattern from Li^6 to A^{36} is taken to indicate that all possible nuclei in this region are known, or unknown ones very rare. Between A^{36} and Cu^{63} there is a low density of points and irregularity, which seem to indicate unknown nuclei. A parallelogram pattern for these higher nuclei indicates many unknown nuclei. The structure of the nucleus is then considered on the lines of the hypothesis that it consists of helium nuclei, internal binding electrons, external protons, and external electrons, and it is shown that the isotopic isobars Io^{230} and UY may be expected.

Science and Curative Medicine.

IN the fifth Stephen Paget Memorial Lecture before the Research Defence Society (*Quart. Jour. Research Defence Soc.* summer issue), Dr. H. H. Dale gave some examples of the effect of research on curative medicine. After referring to the founder of the Society, in memory of whom the lecture was instituted, Dr. Dale pointed out the remarkable change which had come over therapeutics in the last thirty years. Not only have new drugs been introduced after experimental trial in the laboratory, but also the investigation of old drugs, found to be of use empirically, has resulted in explanations being obtained for their actions, so that they can be prescribed with confidence that they will be of value, rather than with the pessimism which feels that at any rate they will do no harm. Only passing reference need be made to insulin, salvarsan, ipecacuanha and emetine, as their therapeutic efficacy is so well known: but it might be pointed out that the experimental investigation of emetine led to the differentiation of the different dysenteries, for only one of which emetine is a remedy, and finally to the development of a method of cultivating the amœbæ *in vitro*, so that new substances likely to be of value in amœbic dysentery can now be tested first in the test-tube, without the use of experimental animals other than the amœbæ themselves.

Many active remedies are mixtures of different chemical compounds, which it is often impossible to separate by chemical means: even when prepared synthetically in the laboratory, it is not always possible to obtain them in the pure state, free from toxic or inactive by-products: their potency can only be determined by tests on animals or tissues obtained from them. Among these may be mentioned immune sera, the extract of the posterior lobe of the pituitary gland, insulin, salvarsan. Until the potency of pituitary (posterior lobe) extract was controlled under the Therapeutic Substances Act, 1925, one extract might be eighty times stronger than the weakest of a series. Nowadays all are standardised in terms of the International Unit, which is the same amount of activity, whatever preparation is used. Recently a particular make of foreign insulin sold in Great Britain for a short time was imperfectly standardised by animal tests: reports were received that patients relapsed into diabetes because the batch used was too weak, or suffered from dangerous symptoms because another batch was too strong. Animal tests indicated that the batches might be 40 per cent weaker or 60 per cent stronger than the indications on the labels. The controlling authority under the Therapeutic Substances Act had power to deal with this situation, and no more of such inadequately standardised insulin has been distributed. Insulin would never have come into practical use without control of its activity by regular tests on animals: if such tests were now abandoned, it would lose the greater part of its value in the treatment of diabetes.

In concluding his lecture, Dr. Dale referred to the work of the National Institute for Medical Research in preparing international and British standards for remedies requiring biological test and in developing suitable methods of assay; as well as to the researches being carried out in virus diseases.

Activity Coefficients and the Debye-Hückel Equation.

DISCREPANCIES between experimental results and calculations from the Debye-Hückel equation are known to exist even at high dilution with salts of higher valency, as well as for univalent types in non-aqueous solvents. Gronwall, La Mer, and Sandved have assumed that the incomplete mathematical solution of the Poisson-Boltzmann equation as given by Debye and Hückel might explain part at least of the discrepancy. They deduce, as a further approximation, the equation for the activity coefficient of a salt of symmetrical valency type:

$$\log f = \frac{-\epsilon^2 z^2}{kTDa} \cdot \tfrac{1}{2} \cdot \frac{x}{1+x} + \sum_{m=1}^{\infty} \left(\frac{\epsilon^2 z^2}{kTDa}\right)^{2m+1} \left[\tfrac{1}{2} X_{2m+1}(x) - 2m\, Y_{2m+1}(x)\right]$$

in which ϵ, z, k, T, D have the usual significance in the Debye-Hückel theory; $x =$ 'a' k, where 'a' is the distance of closest approach of the ions; and $X(x)$, $Y(x)$ are functions of x defined and tabulated through the fifth approximation, that is $m = 2$.

For values of $a/z^2 > 1{\cdot}5$ A., only the first term of this expression, corresponding to the Debye-Hückel approximation, is usually required, but for lower values, corresponding to 'a' < 6 A. for a bi-bivalent salt, the contribution of higher terms cannot be neglected. In low dielectric solvents the higher terms become important, and may even predominate over the first approximation even for 1, 1 valent types. The general solution should yield positive and physically reasonable values for 'a' which are constant over a legitimate concentration range.

La Mer and Parks, in the June number of the *Journal of the American Chemical Society*, describe experiments with cells involving the process $Cd + PbSO_4 = Pb + CdSO_4$ (using cadmium and lead amalgams), which were in good agreement with the theory for the region 0·0006 to 0·01 molal, and yielding positive constant (3·6 A.) values of 'a' which are physically plausible. The Debye-Hückel approximation gave impossible values of 'a'. If cadmium sulphate is dissociated incompletely in the classical sense, this influence on the activity coefficient is too small to be detected below 0·01 molal. It is also shown that 'a' is practically independent of temperature, so that hydration is probably not included in it.

Scatchard, in the same journal, points out that it is incorrect to calculate the heat of dilution from the interionic force formula by differentiation at constant volume, since the experimental data refer to constant pressure. The difference between the two heat quantities is small and can be determined, that between the two dielectric constants is probably also very small, but that between the temperature coefficients at constant pressure and constant volume is generally more important. The calculations are, therefore, made for constant pressure, which involves the addition of a term dependent on the thermal expansion of the solution. The difference is said to amount to about the error of measurement of heat of dilution in very dilute solutions. In the calculation the dielectric constant is assumed independent of concentration, but the extended calculation of Gronwall, La Mer, and Sandved referred to above is applied instead of the simple limiting law of Debye and Hückel. Even in the use of the limiting law, however, neglect of thermal expansion is shown to lead to considerable error.

Archæology and Surveying in Southern Rhodesia.

WE have at times had occasion to refer to difficulties placed in the way of archæological and ethnological research owing to vexatious regulations imposed by the governments of the countries in which research is to be prosecuted. It is not often that the other side of the picture is presented, and that an accredited expedition is known to have abused the privileges that have been granted. Our attention has been directed to a particularly flagrant case. The official report of the Debates of the Legislative Assembly of Southern Rhodesia for May 7 records a reference to the case of Dr. Frobenius, who, it will be remembered, conducted an expedition in Rhodesia in 1929 and communicated some of the results of his investigations at Zimbabwe and elsewhere to the South African meeting of the British Association in that year. Dr. Frobenius, it is stated, was in receipt of substantial assistance from the Government of Southern Rhodesia. A money grant of £92 : 4 : 0, representing half the costs, was supplemented by an equivalent share borne by the railways, and, in addition, a native commissioner was granted six weeks leave on full pay to assist him.

Notwithstanding the fact that, in return, Dr. Frobenius entered into an agreement to share any finds equally with the Government and to submit any specially valuable find to arbitration, the whole of the relics found were removed from the country without the knowledge of the Government. When this was condoned on the condition that they were divided up at Cape Town, they were removed to Germany. Since then Dr. Frobenius has returned such objects as he considers the share of the Government, and has refused either to return or to submit to arbitration the only gold object stated by him to have been found within the Colony. The Colonial Secretary, in making a statement on the matter, was good enough to contrast the action of Miss Caton-Thompson, on behalf of the British Association, in returning all her finds to the Colony.

According to the official report of the debates in the Legislative Assembly of Southern Rhodesia, in the debate on the estimates the deletion was moved of the item "Geodetic and Secondary Triangulation, £5000." In defending the appropriation the Minister of Agriculture and Lands pointed out not only that every self-respecting colony undertakes work of this kind as early as possible in its history, but also that had Southern Rhodesia started it earlier a great deal of money would have been saved. It would appear that much of the present cost of the Geological Survey is due to the fact that, before the Geological Department can pursue its legitimate work of mapping the geological formations, much preliminary work has to be done, which is made necessary by the fact that there is no Ordnance Survey to which reference can be made. Indeed, it was stated by another member that the surveyors who are engaged in the work of triangulation often have to refer to the Geological Survey for information. The Minister also referred to the position in the Union of South Africa. In the Boer war it was found that the maps of the country were utterly defective and a reproach. Immediately after the Union a triangulation of the whole country was begun, and the expenditure now stands at £20,000 a year. The result is that, as the Director states, the triangulation of the Union, which is just about completed, is as fine as any in the British Empire. The motion to delete the appropriation was withdrawn.

In the same debate reference was made to expenditure on afforestation, in which Southern Rhodesia is also pursuing a forward policy. Indeed, throughout the debates it is encouraging to note that the members of the Legislature are fully alive to the advantages of the application of science to the development of the colony, even if not immediately remunerative.

Exhibition of British Optical Instruments.

THE Loan Exhibition of British Optical Instruments which was opened at the Science Museum, South Kensington, on Aug. 28, will remain on view until the end of October, and will provide the public with an opportunity to see collected together in a comparatively small space representative exhibits contributed by most of the important optical firms in Great Britain.

Binoculars are very adequately represented by the exhibits of Messrs. Ross and Messrs. Barr and Stroud, among those of the former being a three power prism binocular telescope with objective aperture of 60 mm. Telescopes are exhibited by Messrs. Ross and Messrs. W. Ottway and Co., the latter firm showing also a selection of stainless steel mirrors. Photographic objectives designed for special purposes, such as aerial photography, the projection and taking of cinema pictures, etc., have received considerable attention by British manufacturers in recent years, and these are included in the lenses shown by Messrs. Ross and Messrs. Taylor, Taylor and Hobson. A portable cinematograph, taking standard size films, is notable amongst Messrs. Ross' exhibits.

Among the surveying instruments is the Tavistock theodolite, reading to one second of arc, which is made by Messrs. Cooke, Troughton and Simms, who are also exhibiting a 45° prismatic astrolabe. This instrument has been designed for the accurate determination of latitude and longitude on shore, and has been used with marked success by the Hydrographic Service of the Admiralty. Messrs. E. R. Watts and Son are showing a selection of 'constant' bubbles, the air-bells of which remain the same length over a wide range of temperature, a vertical magnetic force variometer, and various surveying instruments. A selection of 'Heath' sextants is shown by Messrs. W. F. Stanley and Co.

The collection of microscopes includes a new binocular instrument made by Charles Perry, according to the design of Prof. D. M. S. Watson, of University College, London, and a new model Vickers projection microscope. The latter, which is of very robust design, taking objects up to 50 lb. in weight, can be used for opaque or transparent objects at magnifications of from 3 to 5000 diameters, and is fitted up for demonstration. Other firms exhibiting microscopes are Messrs. J. Swift and Sons, Messrs. C. Baker, and Messrs. W. Watson and Sons. The last-named firm is exhibiting also a selenium densitometer, designed by the British Photographic Research Association, for determination of the density of photographic negatives.

An aerial camera, of a type which has been used all over the world, is exhibited by the Williamson Manufacturing Co. This takes 100 photographs (9 in. × 7 in.) with one filling. Topographical stereoscopes designed for use in examination of aerial photographs for surveying purposes are shown by Messrs. Barr and Stroud.

A small model Hilger interferometer for the correction of prisms and lenses is fitted up to show the optical imperfection of a piece of glass, and a strain viewer by the same makers is arranged to show strain in a glass tumbler. In addition to a spectrographic outfit for metallurgical analysis, Messrs. Adam Hilger are exhibiting an outfit for spectrophotometry in the ultra-violet region of the spectrum. Messrs. Bellingham and Stanley also are showing a spectro-photometry outfit. This apparatus assumes a special interest just now in connexion with the spectral test employed by Dr. Bendien in his experiments on cancer diagnosis. This consists of a spectrograph with quartz optical elements, and a photometer of the sector type driven by an electric motor; the photometer design is based partly on the suggestions recently made by H. J. McNicholas in the Bureau of Standards *Journal of Research*, vol. 1, pp. 942-949. Absorption measurements are obtained by taking a number of exposures, each with a different opening of the variable sector. On the resulting photograph, positions are found in each spectrum where the amount of light passing through the tube of solution is equal to that passed by the variable sector, and from the data obtained an accurate absorption curve can be obtained. Polarimeters for use in the visible and ultra-violet are shown by both these makers.

A rangefinder by Messrs. Barr and Stroud, specially adapted for short ranges in the Museum, is fitted up for demonstration. The internal construction of a rangefinder and various optical parts used in the construction are also shown.

Price catalogues of the instruments in the exhibition are available to the public.

The exhibition is on view during the normal opening hours of the Museum, namely, Mondays, Tuesdays, Wednesdays, Fridays, 10 A.M. to 6 P.M.; Thursdays and Saturdays, 10 A.M. to 10 P.M.; Sundays, 2.30 P.M. to 6 P.M.

Evolutionary Tendencies in the Jaws and Teeth.

DURING the recent International Orthodontic Congress in London, Prof. Elliot Smith delivered an address on "Evolutionary Tendencies in the Jaws and Teeth". He pointed out that, in the human child, there is a delay of four years after the milk teeth have erupted before the permanent teeth commence to appear, and a further ten to fifteen years are required to complete its dental equipment. Up to the seventh year, that is, during the pause between milk and permanent teeth, the child is growing a very large brain, and, again, for a further period of fifteen years or so, when his dental affairs are relatively sluggish, he is learning how to put his complicated cerebral equipment to its fullest biological uses. During this period he develops a chin, because the growth of the tooth-bearing part is restrained by the long delay in the eruption of his teeth. The delay in tooth and jaw development is undoubtedly due to the growth of the brain and the subsequent development of its full functions, which disturbs the orderly process of uniform growth of the jaws and eruption of teeth.

In the apes, the process of eruption of the second teeth follows more closely on that of the first teeth; the second permanent molars erupt before the deciduous molars are replaced by the premolars. Dr. Degerøl, of Copenhagen, has recently pointed out that, in Neanderthal man, the simian type of sequence was still retained in the eruption of his teeth. There are reasons for inferring that the defective chin development of Neanderthal man may be associated with this fact—that the precocious cutting of his teeth permitted the tooth-bearing part of the jaw to keep pace more nearly with the growth of the rest of the jaw and preclude the development of a chin.

In the evolution of man from his simian ancestors the two fundamental structural advances were the great growth of the brain and the changes in the facial region culminating in the development of a chin. To the consequences of these evolutionary changes must be ascribed the origin of the problems of orthodontia. There is no just reason for the belief that the reduction or absence of the third molar is a sign of the early disappearance of this tooth in the human species, or that dental troubles, such as crowding and displacement of teeth, are due to evolutionary changes now active.

University and Educational Intelligence.

CAMBRIDGE.—At St. John's College the following research exhibitions have been awarded: for biochemistry, M. C. Franklin, Canterbury Agricultural College; for experimental physics, R. H. Sloane, Queen's University, Belfast.

THE City and Guilds of London Institute gives prominence in its report for 1930 to the work of the South London Technical Art School established at Kennington in 1879 for training persons engaged in the art industries of the locality, which were chiefly modelling from terra cotta, and for the study of architectural decoration. The school occupies a unique and useful place and has trained the majority of the leading sculptors and some of the foremost painters in Great Britain. The Engineering College was attended by 522 students, a larger number than in any of the four preceding years, and the number of first-year diploma and undergraduate students and of special and post-graduate students was larger than in any year since before the War. The number of candidates examined at the Institute's technological examinations in Great Britain and Ireland and overseas (chiefly in India and Ceylon and New Zealand) increased, respectively, to 14,721 (more than in any year since the War) and 1608.

SOME trends in recent scientific research in America are reflected in statistics of the doctorates conferred in the sciences in American universities. These have been tabulated year by year since 1919 by the National Research Council, the annual bulletin of which on the subject constitutes a useful index to the relevant theses. The total number of these doctorates has increased every year, rising from 336 in 1921 to 1055 in 1930. Of the subjects of the 1055 theses on which science doctorates were conferred last year, about one-third are, as usual, in the field of chemistry. Next comes zoology with 100. Psychology has dropped from 112 to 92 and physics from 101 to 89. All previous records were broken in botany (81), mathematics (74), geology (63—previous record 45), engineering (49), physiology (46), geography (17), whilst the following universities conferred more science doctorate than they have ever done before: Wisconsin (86), Cornell (80), Michigan (55), Ohio State (50), Massachusetts Institute of Technology (29), Pittsburg (15), Virginia (12), Indiana (11), Kansas (11).

Birthdays and Research Centres.

Aug. 26, 1860.—Sir Thomas Ranken Lyle, F.R.S., formerly professor of natural philosophy in the University of Melbourne.

During the last ten years, in addition to being associated in many public utilities, both industrial and educational, I have, in conjunction with my private assistant, Mr. Z. A. Merfield, been carrying on researches aiming at the improvement of diffraction gratings and microscopic test-rulings. The late Mr. Grayson's ruling machines, which I purchased from his executors, have in many respects been reconstructed and improved.

We have developed a type of speculum metal with a high reflecting power which is untarnishable, and we can prepare and polish the ruling diamond so as to have any desired operating faces. Thus we are able to produce gratings by which the major portion of the incident light is diffracted into any desired spectrum.

We have supplied rulings to different research institutes, on speculum for optical work and on glass for X-ray investigations. We have also succeeded in producing microscopic rulings for ultra-violet investigations with rulings at rates up to 250,000 an inch.

The work is being continued; at present, on further improvement of speculum and on more accurate temperature control of the ruling chamber.

Sept. 23, 1850.—Prof. Richard Hertwig, foreign member of the Linnean Society of London and formerly professor of comparative anatomy and zoology in the University of Munich.

Zurückblickend auf die sechsig Jahre meiner zoologischen Thätigkeit, empfinde ich es als ein grosses Glück, dass in diesen Zeitraum der gewaltige Aufschwung fiel, den die Biologie dem Wirken Darwins verdankt. Dieser Aufschwung kam zunächst der Morphologie zu Gute, der vergleichenden Anatomie und Entwicklungsgeschichte. In den letzten Jahrzehnten folgte die experimentelle Zoologie, die exacte Erblichkeits- und Variabilitätsforschung und die vergleichende Physiologie.

Mir will es sogar scheinen, als ob durch die grossen Erfolge der experimentellen Zoologie die morphologischen Probleme allzusehr in den Hintergrund gedrängt würden. Lange Zeit mit experimentellen Untersuchungen beschäftigt, habe ich mich neuerdings wieder der Morphologie der Radiolarien zugewandt und mich überzeugt, wie viel Interessantes hier noch zu entdecken ist. Die Morphologie bildet die Basis, auf der die Physiologie weiter baut. Wir müssen trachten, diese Basis ständig zu verbreiten und zu sichern. Damit werden wir auch der Palaeontologie und Thiergeographie gute Dienste leisten.

Sept. 23, 1850.—Prof. W. Mitchinson Hicks, F.R.S., emeritus professor of physics in the University of Sheffield.

I should like to publish a new edition of my "Analysis of Spectra", which is now out of print; but the advances in real observational knowledge and in that of spectral relationships since its appearance in 1922 are so enormous that it would be hopeless at my age to attempt it. I am anxious, however, to put into form for publication a connected account of the fundamental quantitative relations in spectra contained in that book and of new data in support.

Sept. 24, 1874.—Prof. Alex. Findlay, professor of chemistry in the University of Aberdeen.

The fact that Pasteur's method of resolving racemic compounds by crystallisation from solution has found application in only a small number of cases, provoked the investigations in which I have been engaged in recent years. What connexion, if any, exists between the constitution of a racemic compound and its stability relative to that of the active antipodes, and what are the factors which influence the temperature at which the relative stability of racemic and active forms undergoes change? Answers to these questions have been sought by a study of freezing point and solubility curves.

I have also been much interested in the pædagogy of chemistry, and in my leisure time I am collecting materials for a history of chemical teaching in Aberdeen.

Sept. 24, 1865.—Prof. C. F. Jenkin, formerly professor of engineering science in the University of Oxford.

I am chiefly interested in investigations on the fatigue of metals and building materials; and in earth pressures.

Sept. 26, 1881.—Mr. P. P. Laidlaw, F.R.S., pathologist to the Medical Research Council.

I am at present engaged on the improvement of dog distemper anti-serum and the separation and purification of the most active constituent of whole serum, so that a therapeutic product of high potency can be secured at will. It is hoped that the knowledge gained from this study may be of assistance in the production and improvement of anti-sera for other virus diseases.

The outstanding problem for the research worker in virus diseases is believed to be luxuriant cultivation of viruses, apart from living cells, and it is hoped that many workers will endeavour to solve this problem.

Societies and Academies.

London.

Institute of Metals, Sept. 14 (Annual Autumn Meeting, Zurich).—**H. Waterhouse** and **R. Willows**: The effects of cold-rolling and of heat-treatment on some lead alloys. The hardness numbers of the cast alloys ranged from 5 to 18 Brinell. Cold-rolling hardened the soft alloys and softened the hard alloys, the hardness immediately after cold-rolling lying in all cases between 8 and 11 Brinell. Most of the alloys, especially those containing cadmium and antimony, were re-hardened to approximately the 'as cast' hardness by suitable heat-treatment, quenching and ageing. Certain alloys age-hardened after air-cooling or even more restrained cooling from the heat-treatment temperature. The age-hardness persists for several months at least, but is destroyed by severe cold-working and self-annealing.—**H. Sutton** and **L. F. Le Brocq**: The protection of magnesium alloys against corrosion. Of the methods of protection examined the most promising appeared to be that of chemical treatment of the surface followed by the application of lanolin or a suitable enamel.—**D. G. Jones**, **L. B. Pfeil**, and **W. T. Griffiths**: Nickel-copper alloys of high elastic limit. The elastic limit is low in substantially pure nickel-copper alloys in the fully annealed and in the cold-drawn conditions, but high elastic limits are developed in all compositions as a result of low temperature heat-treatment following cold-working. High elastic limits may also be produced in nickel-copper alloys containing small amounts of such elements as silicon, which render the alloys susceptible to heat-treatment.—**D. Hanson** and **I. G. Slater**: Unsoundness in aluminium sand-castings. (1) Pin-holes: their causes and prevention. To eliminate pin-holes treatment with nitrogen or with chlorine is sometimes successful, but cannot always be relied upon to produce castings perfectly free from pin-holes; titanium tetrachloride is effective with 'Y'-alloy, but was found to be less certain with other alloys, although the grain-refinement which it produces may make the pin-holes very small without reducing the total volume of the cavities. The most generally successful method is treatment with a mixture of equal parts of nitrogen and chlorine, by means of which all the alloys examined could be made practically sound by a treatment of twenty minutes' duration at 700° C.—(2) The effects of using metal previously subjected to corrosive conditions. The extent and amount of unsoundness produced depends upon the type and time of exposure, and also upon the particular alloy examined. The suggestion is made that the deterioration is the result of electrolytic action on corrosion, involving the liberation of hydrogen in the nascent state which is absorbed by the metal. On re-melting and casting, the hydrogen is evolved in the molecular condition and produces pin-holes.—**William Hume-Rothery**: The macro-etching of aluminium-silicon alloys. The macrostructure of aluminium-silicon alloys can be revealed satisfactorily by means of a solution of cupric chloride containing 150-160 gm. per litre. Etching is carried out by immersing the specimen several times in the copper chloride solution, the deposit of copper being removed between each immersion. A final brightening can be obtained by treatment with a dilute solution of chromic acid.—**J. E. Newson** and **A. Wragg**: Note on the failure of a high-strength brass. The reeling process for straightening, after extrusion, in the case of a brass with a high yield-point, is responsible for residual stresses of such an order that failure due to internal cracking may result during storage or on subsequent machining.

PARIS.

Academy of Sciences, July 27.—**C. Camichel**, **C. Crescent**, and **L. Escande**: Contribution to the study of intermittent springs with underground gallery. Experimental study of the causes of variable flow.—**J. Pasquier**: The equations $s=f(x, y, z, p, q)$, integrable by the method of Darboux.—**Edouard Callandreau**: The conjugated points of de Fontviolant's equation of elasticity.—**Alfred Rosenblatt**: The stability of laminar movements of viscous incompressible liquids. —**Henri Mineur**: A new method for the study of galactic rotation.—**Pierre Guintini**: The movement of rotation of the *B*-type star ensemble.—**P. Biquard**: The absorption of ultra-sound waves by water.—**Paul Bizos** and **Tarlé**: The unification of all forms of string instruments.—**R. Guyot**: The reflection of very short electromagnetic waves. Pierret oscillators furnish a means of obtaining short electromagnetic waves, 12-20 cm. in length. The reflection of these short waves by water and by saline solutions has been studied. Results are given for water and for fourteen salt solutions, containing up to 13 per cent of common salt.—**Léon Bloch**, **Eugène Bloch**, and **Pierre Lacroute**: Multiplets in the spark spectrum of bromine (Br II).—**C. Marie** and **N. Thon**: The measurement of the stresses of electrolytic deposits of metals.—**Charles Liagre**: The theory of the lead accumulator. The experiments described lead to the conclusion that the classical equation PbO_2+Pb+ dilute sulphuric acid in excess$\rightleftharpoons 2PbSO_4+$dilute sulphuric acid is a true expression of the facts.—**R. Lespieau**, **M. Bourguel**, and **R. L. Wakeman**: The Raman effect in chemistry. The sensibility of organic spectrum analysis. Analysis by the Raman spectrum, improved by the use of the Chalonge and Lambert microphotometer, detects a very small quantity of an ethylenic hydrocarbon in the presence of cyclo-hydrocarbons, and can determine the proportion of the former to about 1·3 per cent.—**M. Prettre**: The ignition of mixtures of acetaldehyde and air. These mixtures show a double ignition point similar to the air-hydrocarbon mixtures previously described. The lower point can be suppressed by the addition of an antidetonant such as lead ethyl.—**Charles Dufraisse** and **Marius Badoche**: Researches on the dissociable organic oxides. The hydrocarbon produced by the removal of a phenyl group from rubrene. The compound obtained by the prolonged action of the Grignard reagent on iso-oxyrubrene, although a phenyl group has been removed, still retains the essential characters of rubrene.—**Paul Fallot**: The geology of the neighbourhood of Xauen (Spanish Rif).—**Jean Risbec**: A parasite of the spring caterpillar of the cotton plant (*Earias huegli*).—**Georges Bourguignon**: The relations of vestibular chronaxy with emotivity, in the normal state, in pseudo-Mongolism and in dementia præcox.—**E. Brumpt**: Pruritis and dermatitis produced in bathers by the cercariæ of fresh-water molluscs.—**A. Blanchetière**: The action of pepsin on the solutions of monamino-acids, isolated or mixed.—**Georges Blanc** and **J. Caminopétros**: Experimental researches on the sensibility of domestic animals, carriers of *Rhipicephalus sanguineus*, to the virus of exanthematic fever. Domestic animals (dog, rabbit, rat, pig, sheep, pigeon), normal carriers of *R. sanguineus*, are not sensible to the virus of exanthematic fever. The fact that the virus of this fever is transmitted by *R. sanguineus* to its descendants proves that exanthematic fever in the Mediterranean region is an infection of the tick of the dog, without any domestic animal acting as a reservoir of the virus.—**Marcel Labbé**, **Maurice Villaret**, **L. Justin-Besançon**, **Mlle. D. Kohler**, **Mme. Schiff-Wertheimer**, and **P. Soulié**: Preliminary researches on certain protrusions of the eyeball, especially Basedowian exophthalmia.

LENINGRAD.

Academy of Sciences, *Comptes Rendus*, 1931, No. 3. —**A. Tsvetkov**: On the fundamental psycho-physical law. A formula is offered to express the relation between the intensity of the stimulus and the number of the excited nerve cells.—**J. Orlov**: The remains of a primitive representative of Pinnipedia from the neogene deposits in western Siberia. The remains have been found in fresh-water neogene deposits near Pavlodar. The animal is described under the name *Semantor macrurus* g. et sp. n., and regarded as belonging to a new family Semantoridæ, which differs more from the three known families of Pinnipedia than these families differ between themselves.—**K. K. Flerov**: (1) A review of the elks (*Alces* Gray) of the Old World. Three subspecies of *Alces alces* L. are distinguished, namely, *A. alces alces* L. distributed from western Europe as far east as the Yenisei river and the Altai mountains; *A. alces pfizenmayeri* Zukov. (with *jakutensis* Millais and *bedfordiae* Lyd. as synonyms) occurring east of the Yenisei; and *A. alces* subsp. from the Ussuri region.—(2) On the generic characters in the family Tragulidæ (Mammalia, Artidactyla). Three genera of living Tragulidæ are distinguished, namely, *Moschiola*, *Hyemoschus*, and *Tragulus*.—**G. Nadson** and **E. Stern**: The combined action of metals and of X-rays on yeasts. Oligodynamic action of metals on yeasts is altered if the metals act simultaneously with X-rays. In this case the oligodynamic effect of different metals shows an inverse correlation with their atomic weight. —**E. Stern**: The combined action of metals and X-rays on luminous bacteria. Experiments with *Photobacterium phosphorescens* confirmed the results obtained with yeasts (see above).

Standard Meteorological Instruments. (List M.2.) Pp. 140. (London: Negretti and Zambra.)

A Catalogue of Book Bargains. (No. 530). Pp. 16. (London: William Glaisher, Ltd.)

Diary of Societies.

TUESDAY, September 22.

London Natural History Society (at London School of Hygiene and Tropical Medicine), at 6.30.—Mrs. Norman Lowe: A Rambler in Siam.

Quekett Microscopical Club (at 11 Chandos Street, W.1), at 7.

FRIDAY, September 25.

Electroplaters' and Depositors' Technical Society (in Rehearsal Room of the Royal Albert Hall), at 3 30.—Dr. R. S Hutton: The Rise and Early Development of Electroplating (Address).—At 7.30.—D. J. Macnaughtan: Electrodeposition and the Engineer (Address).

CENTENARY.

September 19 to 25.

Faraday Celebrations.

Saturday, Sept. 19 (at Royal Institution).—Reception.

Monday, Sept. 21, at 11.30 A.M. (at Royal Institution).—Informal Meeting.
At 3.—Reception.
At 8 P.M. (at Queen's Hall).—Commemorative Meeting. Speeches by Representatives of Institutions in various parts of the world.

Tuesday, Sept. 22, at 10.30 A.M. (at Kingsway Hall)—Conference.
At 8 30 P.M. (at Royal Institution).—Conversazione.
At 8.30 P.M. (at Institution of Electrical Engineers).—Conversazione.

Wednesday, Sept. 23, at 4.30 (at Royal Albert Hall).—Faraday Exhibition.

Thursday, Sept. 24, at 3 (at National Physical Laboratory)—Garden Party.

Friday, Sept. 25, at 7.45 (at Dorchester Hotel)—Entertainment by H.M. Government.

CONGRESSES.

September 1 to 19.

International Illumination Congress. (For Programme see Nature, Aug. 29.)

September 13 to 18.

Institute of Metals. (For Programme see Nature, Sept. 5.)

September 13 to 19.

International Medical Educational Congress (with special reference to Balneology) (at Carlsbad).

September 16 to 24.

International Geographical Union (at Paris).

September 18 to 20.

National Smoke Abatement Society. (For Programme see Nature, Sept. 12.)

September 18 to 21.

Association of Special Libraries and Information Bureaux (at Lady Margaret Hall, Oxford). (For Progamme see Nature, Sept. 12.)

September 20 to 27.

Institut International d'Anthropologie (at Paris).—Sections: Morphological Anthropology and Study of Races; Human Palæontology and Archæology; Eugenics and Heredity; Psychosociology and Criminology; Ethnography, Folklore, and Human Geography.

September 23 to 25.

Institution of Mining Engineers (at Manchester).

September 23 to 26.

International Climatological Commission (at Innsbruck).

September 23 to 30.

British Association for the Advancement of Science (Centenary Meeting).

Wednesday, Sept. 23, at 3 (in the Royal Albert Hall).—Installation of President.
At 9 P.M. (in Central Hall).—Genl. Smuts: The Scientific World-Picture of To-day (Presidential Address).

Thursday, Sept. 24, at 10 A.M.—Sir J. J. Thomson: The Growth in Opportunities for Education and Research in Physics in the past Fifty Years (Presidential Address to Section A)
Brig.-Genl. Sir Harold Hartley: Michael Faraday and the Theory of Electrolytic Conduction (Presidential Address to Section B).
Prof. J. W. Gregory: Presidential Address to Section C.
Prof. E. B. Poulton: A Hundred Years of Evolution (Presidential Address to Section D)
Prof. A. R. Radcliffe-Brown: Presidential Address to Section H.
Sir Charles Grant Robertson: Educational Development; 1831–1931: A Centenary Retrospect and a Forecast (Presidential Address to Section L).
At 2.—Sir Arthur Smith Woodward: Geology as a Subject for Local Societies (Presidential Address to Conference of Delegates of Corresponding Societies).
At 9 P.M.—Prof. W. A. Bone: The Photographic Analysis of Explosion Flames (Evening Discourse, in Royal Geographical Society's Hall).
Sir P. Chalmers Mitchell. Zoos and National Parks (Evening Discourse, in Royal College of Music).

Friday, Sept. 25, at 10 A.M.—Prof. E. Cannan: The Changed Outlook in regard to Population, 1831–1931 (Presidential Address to Section F)
Sir John Russell: The Changing Outlook in Agriculture (Presidential Address to Section M).
At 10.15 A M.—Sir Halford J. Mackinder: The Human Habitat (Presidential Address to Section E).
At 5.—Sir Alfred Ewing: Presidential Address to Section G and Bramwell Trust Lecture.

Saturday, Sept. 26, at 9 P.M.—Sir Arthur Keith: The Construction of Man's Family Tree (Evening Discourse, in Royal Geographical Society's Hall).
Sir Oliver Lodge: A Retrospect of Wireless Communication (Evening Discourse, in Royal College of Music).

Monday, Sept. 28, at 10 A.M.—Dr. H. H. Dale: The Biological Nature of Filtrable Viruses (Presidential Address to Section I).
Dr. C. S. Myers: The Nature of Mind (Presidential Address to Section J)
Prof. T. G. Hill: The Advancement of Botany (Presidential Address to Section K).
At 3.30.—Dr. A. Macrae: Guidance in the Choice of an Occupation (Public Lecture, at London School of Economics).

Tuesday, Sept 29, at 8.30 P.M.—Dr G. Thilenius: Some Biological Viewpoints in Ethnology (Huxley Memorial Lecture of the Royal Anthropological Institute).
At 9 P.M—Sir James Jeans: Beyond the Milky Way (Evening Discourse, in Central Hall).
Dr S. Kemp: Oceanography in the Antarctic (Evening Discourse, in Royal Geographical Society's Hall).

September 24 to 27.

Swiss Society of Natural Sciences (at La Chaux-de-Fonds and Le Locle).
Prof. A. Piccard: Ascent into the Upper Atmosphere in a Sealed Car attached to a Balloon (Lecture).
Dr. C. Perret: Film on the Life of Bees.
Prof. P. Arbenz: The Geological History of South Africa and Its Camp Sites (Lecture).
Prof. Pérez: Rhizocephalods Parasitic on Hermit Crabs (Lecture).

Science and Humanity.

TO look back over the century's record of the achievements of the British Association for the Advancement of Science is to be reminded once again of the disparity between the achievements of science and its actual control or direction of public affairs. A century which has witnessed the growth of the meeting of 350 enthusiasts at York in 1831, organised by Harcourt, Brewster and others, " to give a stronger impulse and a more systematic direction to scientific enquiry ; and to promote the intercourse of those who cultivate science in different parts of the British Empire " into a powerful Association that the Empire is now proud to honour in its capital for the first time, has seen indeed an immense advance in the respect with which men of science are held by the nation. The disparagement or opposition which the early efforts of the Association encountered, sometimes in unexpected quarters as from Carlyle, have long since passed away, but the brilliant achievements in pure and applied science during the last century have availed scarcely at all to increase the power of science to direct or influence national policy in matters which involve questions of science. While almost all the major problems of administration involve the assessment of scientific factors, lack of appreciation of science remains characteristic of our administrators. Many of Thomas Huxley's persuasive addresses on science, education, and politics remain as pertinent to-day as when they were uttered half a century or more ago.

This situation is one so fraught with danger to civilisation that on this ground alone inquiry into its causes is urgent. Essentially we are faced with a gap between knowledge and power ; a contrast between the comparative freedom with which scientific knowledge and development influence industrial development, and their almost negligible influence in the control of national and international policies which are largely responsible for the development or stagnation of industry and society.

One of the commonest views as to the cause of this situation is that the intense specialisation demanded in scientific work renders the man of science incompetent to undertake administrative work or assess the value of facts outside the narrow sphere of his specialised work. Fundamentally this view is probably an unconscious assertion of the distinction between knowledge and method or use. There is little in our educational system to enable those who receive no scientific training to distinguish science from the mere knowledge of a mass of undigested facts. Knowledge, as a matter of experience, as Sir Arthur Quiller-Couch has said, cannot even be counted upon to educate. The science graduate is no exception to the general tendency of our universities to neglect to teach the use of knowledge—or in other words to relate knowledge and power—and to devote to competitive examinations the energy that were better spent in the production of graduates whose trained judgment as matured by experience we could trust to choose the better and reject the worse.

The mere fact that the growth of knowledge has made selection both more imperative and more difficult lends no support to the plea that we should call a halt in our quest of knowledge, that scientific research might well take a ten years' holiday and our energies be devoted to the utilisation or correlation of knowledge that is already ours. Merely to consider how much mankind might have lost had some such truce to discovery been declared at any time in the last fifty years is to realise the futility and impracticability of that plea. Nature does not lightly reveal her secrets to those who miss their opportunities, and we might still be without the knowledge of radium, of insulin, vitamins, broadcasting, and the motion picture—to mention only recent contributions of science to the relief of suffering or to the amenities of life. To interrupt the quest for knowledge might rob mankind for a generation or more of some vital clue to the control of such a scourge as cancer or to the real causes of the present unemployment and industrial depression.

What is required is not less research but more wisely and widely directed research. Huxley's words in 1854, on the science of society, "a higher division of science which considers living beings as aggregates—which deals with the relation of living beings one to another, the science which observes men, whose deductions lead to our happiness or our misery—and whose verifications often come too late", are strangely echoed in Prof. McDougall's recent plea for the direction of our most powerful intellects from the physical sciences into researches on the biological, the human, and the social sciences; and thus to build the social sciences, especially the science of economics, on the basis provided by anthropological research.

It is admittedly a fundamental defect of our present university training that while teaching the appreciation of facts it frequently fails to impart scientific method, and largely in consequence of this its graduates are sometimes quite unable to assess values, especially human values. The suggestion that the technical expert tends to ignore the human element in a situation and looks exclusively at the functional results of his work, may, in consequence of his imperfect training, be true of the newly graduated, but in the opinion of the Committee of the British Science Guild on the Position of the Technical Expert in the Public Services and Industry, it is completely contradicted in experience. Under industrial conditions, the scientific worker rapidly and readily learns to assess the human factors involved in his projects, and acquires experience in co-operation, compromise and accommodation which early fit him for administrative duties. Abundant evidence could be furnished to show that in spite of defects in their academic training, many scientific workers when afforded the opportunity are in no way inferior in administrative capacity to their fellows who have graduated in arts or classics.

Unfortunately, this defect in the present system of training for the appreciation of scientific values inevitably tends to obscure both the human value of the study of science and what is equally important, the defective teaching of general science to those pursuing a career in arts, law medicine, commerce, or industry generally. On the first point it is pardonable to recall once more Huxley's emphatic conviction that for the attainment of real culture an exclusively scientific education is at least as effective as an exclusively literary education. The science student at least acquires some elementary knowledge of scientific method, of some habits of accurate observation and the rudiments of deductive reasoning. These are the habits and methods which are essential not only to the administrator but also to all who by skilful selection arrive at their own judgments whether on questions of art, science, history, or life. The emphasis on discovery and on verification implicit in all true teaching of science is an invaluable corrective to the bias towards authority which it is so difficult to avoid in the teaching of literary subjects. That alone would justify the claim that a knowledge of science and of scientific method is essential if education is to confer real balance and the power to assess human and other values.

Largely because of our unscientific teaching of science, the human value of science is only slowly being recognised, and biologists are still reiterating the pleading of Huxley two generations ago. To science and to scientific workers more than to any other factor is due the immense improvement in the conditions of work in industry and the elaboration of methods which adapt the machine to man instead of viewing, as the early Victorians did, the operatives as mere cogs in the industrial machine. Beyond this, as Prof. A. V. Hill pointed out in his Henry Sidgwick memorial lecture, we are now glimpsing in psychology the experimental application of biology to problems of national and international conduct, racial relations, including the administration of the backward races, the evolution of co-operation in place of competition, upon the solution of which the fate of civilisation largely turns. Nor have we yet utilised the human values which lie latent in the history of science itself. Scientific workers themselves are apt to neglect unduly the inspiration and teaching which a knowledge of the growth and development of their own science can often give.

It is probable that we here come close to one of the causes of the defective teaching of science to those pursuing other careers. We are still far indeed from Huxley's ideal that

> no boy or girl should leave school without possessing a grasp of the general character of science and without having been disciplined, more or less, in the methods of all sciences, so that they shall be prepared to face scientific problems, not by knowing at once the conditions of every problem or by being able at once to solve it; but by being familiar with the general current of scientific thought and by being able to apply the methods of science in the proper way when they have acquainted themselves with the conditions of the special problem ".

The rapidity with which scientific discoveries in the intervening seventy-two years have transformed the conditions of life make that ideal an objective essential for the security of civilisation. Had scientific workers themselves realised more fully the human value of scientific history, especially biography, much more might have been done to secure a wider and more effective teaching of science. The records of science are full of episodes of courage and endurance, patience, heroism, and resource as stirring as any culled from chronicles of war, politics, or religion. Without the spirit of adventure even in his laboratory the scientific worker would make little progress, and it is among the merits of science that it equips mankind for its migration across uncharted seas of adventure, and assists man to master his surroundings and not merely adapt himself to them.

The neglect of history by scientific workers is, however, completely overshadowed by the neglect of science by history, to which attention was directed at the recent International Congress of the History of Science and Technology. Pointing out that the very success of the application of scientific method and discovery has deflected attention from the process itself, Dr. Singer urged the value of watching its application under other conditions in the past for a full understanding of the process. More than this, it was eloquently urged by Prof. A. V. Hill that if science is to deal with human greatness, with things which have given man control of himself and of his surroundings and have freed him from superstition, ignorance, ill-health, and incompetence in the face of natural forces, the great figures of science and their discoveries deserve a prominent place in all history books.

The service which history can render to science may indeed prove decisive. While, as already suggested, scientific workers themselves might make far more effective use of the opportunities which biography affords them of bringing home to the general community the human aspects of science and its effect on and expression in personality, to the professional historian largely must be left the task of correlating scientific advances in different fields and the main stream of human progress. Only when this task is attempted and the history of science becomes an integral part in the training and discipline of general historical study can science assume her just position in education. It will then no longer be possible for administration to remain exclusively in the hands of those who have no first-hand knowledge of science or any independent capacity to sort the issues when scientific questions are involved in an important administrative decision. We shall have travelled a long distance towards the fulfilment of Huxley's ideal when the extensive science discipline advocated by Sir David Prain finds its place in the arts faculties of our universities and training colleges.

There is perhaps no greater service that the British Association can render to society at its centenary celebrations than by its attention to the human values of science. In looking back over a century of honourable progress, the Association is entitled to point out the high achievements of many of those with whose names it has been associated, the inspiration which their spirit of adventure, of service and of devotion, can give to society, and the part which science has played in shaping the social and intellectual environment in which we live. In the impressive programme of the meetings there is ample evidence of the attention which science is giving to the improvement of conditions of work, and to the application of scientific methods to problems of industrial management and distribution, as well as to the government of native races. Problems of population and of education are to be discussed from the scientific point of view, including the value of such new methods as the cinematograph film both in general and in industrial education, and the application of eugenics in education.

The Association provides scientific workers with an unrivalled opportunity for presenting a constructive programme indicating the contribution which the teaching of science, and especially of scientific method and achievement, may make to education. By emphasising the positive side of science, the inspiration which man derives from its achievements in the conquest of Nature, the assistance which scientific method and scientific knowledge confer in handling not only industrial problems but also social, economic, and administrative problems generally, rather than the defects of our present methods of education with their tendency to encourage premature specialisation, the pursuit of knowledge rather than method and to discourage the development of personality and independence of thought, scientific workers will do much to prepare the way for a century of even greater advances in science. If this is undertaken, seeking, as Colet wrote to More, " not for victory in argument but for truth ", and attempting to set in order the facts of experience, it may well happen that under the leadership of science there may be ushered in a truly scientific age in which personality finds its full play, science and art and literature make their fitting contribution to general culture, and the application of scientific methods enables man to pioneer into yet wider realms in search of truth and mastery over Nature.

When scientific achievements in the conquest of Nature have received their full meed of acknowledgment, it is the spirit of science that is all-important to mankind. The accumulation of knowledge signifies little. The science of one age, as Dr. Singer wisely says, becomes the nonsense of the next, but the spirit of science leads man forward continually to fresh conquests over his changing environment. From the labours of scientific workers as of others may we hope some day to understand better what is involved in the toilsome path which humanity still has to tread towards the goal of civilisation—in Seebohm's phrase the art of living together in civilised society —and to finding that, as in More's " Utopia ", a fearless faith in the laws of Nature consorts well with a profound faith in man's noblest ideals.

Problems of the Mineral Industry.

Minerals in Modern Industry. By Dr. Walter H. Voskuil. Pp. ix + 350. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1930.) 18*s.* 6*d.* net.

THE industrial revolution which began in England spread to the western countries of the Continent and developed because of favourable conditions of mineral resources. These natural conditions were found to be reproduced on a larger scale on the other side of the North Atlantic and the new industries became transplanted there also. Three centres—northern England, the Franco-German district bordering the Rhine valley, and the north-eastern United States—became the world's workshops: they embrace more than ninety per cent of the world's iron and steel-making capacity. Once established, the inertia of invested capital helped to maintain production. Other types of industries, notably the chemical, found it convenient to locate close to the steel centre. The increasing density of population enhances the local market for manufactured products. Raw materials, including accessory minerals, flow to these three centres from all over the globe.

The demand for minerals becomes ever greater, producers have been supplying a market which each year exceeded the year preceding in its demands. The needs of the War and the post-War expansion period were met by expansion of production and of capacity to produce to such a degree that, first with a return to normality and now to a condition far below normal, heroic measures must be attempted to find outlets for the products of the mines and even to save them financially.

The urge to consume, the use of every form of persuasion and advertisement, have been directed towards trying to keep in motion as much and as many as possible of the material goods that have been produced. One of the effects of this campaign has been to increase the costs of distribution in greater and greater proportion so that often they exceed those of manufacturing, not only absorbing all the profits but also imposing a greater deadweight of oncost when production is slack. The salesman has become more important than the technician.

The remedy, to fit production to the needs of the market, implies control of output in minerals as in other products, but the problem is simpler to suggest than to solve.

The question of control of production leads directly into the broader problem of the conservation of mineral resources. Minerals are wasting assets, and although, taking the world as a whole, there is no need to be alarmed at the depletion of natural stores, yet the acceleration of production during the last twenty years is sufficient to indicate the wisdom of taking stock. The living generation may always be expected to take all it needs, and deliberate curtailment of any particular mineral is only brought about by raising the price to a point when some alternative is favoured. There is a duty, however, to eliminate needless waste and to initiate research into economy of use.

Work to this end is going on with every mineral; more efficient methods of mining, of extraction, of utilisation, of recovery and re-use, are brought forward every day. In coal alone the progress is enormous: electric energy is produced to-day with half the weight of coal per unit required ten years ago and it will be halved again. It is safe to forecast that the same effect could be gained with half the coal at present burnt in England if it were used in the most up-to-date apparatus. Every coal strike, every increase in price, give new impetus to such a movement.

Gold and tin are the chief minerals of which the prospect of a declining output is admitted. The former is the foundation of a monetary system which, judging by to-day's chaos, has failed and will perhaps be replaced. Tin is mainly used for containers in contact with foods, but it is certain that the march of research and invention will find substitutes for this, either aluminium or possibly even cellulose acetate or lacquered containers. Indeed, we are only at the beginning of the potential discoveries in connexion with the addition of small quantities of so-called rare elements to metal alloys, whilst we shall not be content very much longer to make structural steelwork of a metal which rusts so quickly as to require regular painting. Research will prove a certain palliative for possible mineral shortage.

The critical minerals are the energy resources—coal, oil, natural gas: these at least must not be wasted. A close control on their use is imposed, however, by each fractional increase in price, and a period like the present when wasteful competition is causing them to be sold at entirely uneconomic prices is not likely to last. Water power, energy from the sea and from the sun, are all available when real economy is necessary.

No one nation contains a full variety of the essential minerals. Those missing can be obtained by the vigilance of governments or of manufacturing interests in securing control of concessions in other lands, but whilst insuring the domestic position, no nation can deprive its neighbour of needed minerals without inviting trouble. The War was fought above the coal and iron mines of France, Belgium, and Lorraine; the unequal geographical and political control of mineral resources forms a background of menace to the maintenance of peace.

Such are the problems envisaged by Dr. Vosguil, his book containing an exposition of the facts relating to the chief minerals: it will well repay careful reading throughout by all connected, in whatever way, with them.

E. F. ARMSTRONG.

A Chinese Alchemist.

The Travels of an Alchemist: the Journey of the Taoist Ch'ang-Ch'un from China to the Hindukush at the Summons of Chingiz Khan. Recorded by his Disciple, Li Chih-Ch'ang. Translated with an Introduction by Arthur Waley. (The Broadway Travellers.) Pp. xi + 166. (London: George Routledge and Sons, Ltd., 1931.) 10*s.* 6*d.* net.

MR. WALEY provides an English translation of the "Hsi Yu Chi", made directly from the Chinese text. In a valuable introduction of 40 pages he deals with Mongol history and philology, and illuminates the history of medieval Taoism with the light of the Taoist Canon, which has become freely available to European scholars since its re-publication in 1923–25. He points out that the new Taoism, created by Chang Tao-ling in the second century A.D., rendered a great service by preserving texts and doctrines of philosophy, astrology, alchemy, hygiene, etc., which Confucianism rejected as heterodox. He sums up the connexion between Taoism and alchemy in the following words:

> "In one branch of study the Taoists were unique. To them alone is due the vast body of alchemical literature, which makes the Chinese sources more important than even the Mohammedan to the historian of this strange subject. The Chinese had inherited from the remote past the belief that certain substances such as jade, pearl, mother-of-pearl, cinnabar, were life-giving, and that if absorbed into the body they would prevent the gradual deteriorations of old age. As they exist in nature, however, these substances, it was thought, are always 'impure'. Only when made artificially can they be safely and efficaciously ingested. In early China gold was not highly valued. When through contact with the gold-prizing nomads of the north-west the Chinese, in the three or four centuries before the Christian era, began to accept gold as their highest standard of value, the ideas previously attached to other

'life-giving' and consequently valuable substances became associated also with gold. Thus arose various distinct forms of alchemy: (1) the attempt to produce a liquid gold that could be drunk and so produce longevity; (2) the so-called 'Gold-cinnabar' alchemy. To the recipes for making artificial cinnabar and thus producing an elixir of life was arbitrarily added the further clause that 'when the cinnabar is made, gold will easily follow'. We thus see the new life-giving substance gold tagged on to the beliefs connected with the older substance, cinnabar. (3) An attempt, parallel to that of the earliest Western alchemy, to produce gold from baser metals such as lead."

These ideas are of particular interest to students of the origins of alchemy, who, during recent years, have devoted increasing attention to the nature and scope of Chinese alchemy.* According to Mr. Waley, an alchemy of gold existed in China so far back as the first century B.C. In extant alchemical treatises of the fourth century A.D., Pao P'u Tzu discriminates between the three kinds of alchemy quoted above. In the tenth century exoteric alchemy (*wai tan*) merged into esoteric (*nei tan*), the 'souls' or 'essences' of mercury, sulphur, lead, etc., bearing to the common metals the same relationship as the Taoist, adept, or perfected man, bears to common mortals. A further evolution had been reached at the end of the eleventh century, the transcendental metals having become identified with various parts of the human body. Thus,

> "alchemy comes to mean in China not an experimentation with chemicals, blowpipes, furnace and the like (though these survive in the popular alchemy of itinerant quacks), but a system of mental and physical re-education. It was in this sense that Ch'ang-ch'un, whose travels are here recorded, was an alchemist, and it is a mysticism of this kind that is expounded in his 'Straight Guide to the Mighty Elixir'."

The reader who takes up this book in the expectation of gathering at first hand the views of the adept Ch'ang-Ch'un upon orthodox alchemy will thus be disappointed: the narrative contains little of alchemical interest. There is ample compensation, however, in the light it throws upon the character of the 'Master', and in the picturesque glimpses it affords of varied Eastern races, manners, and customs, in the early thirteenth century. "Leaving the crowded Chinese plains, we see the Mongol nomads with their waggons and flocks, their fur-trimmed coats and strange head-dresses, then the turbaned Moslem ploughman, the cosmopolitan crowds of Samarkand and the wild tribesmen of Afghanistan."

The translator points out that the "Hsi Yu Chi" is true to type in the highly impersonal treatment of its theme. Notwithstanding this, we are able to build up from it an intimate picture of the 'Master', Ch'ang-Ch'un. In Sun Hsi's preface, written in 1228, we read that "he sat with the rigidity of a corpse, stood with the stiffness of a tree, moved swift as lightning and walked like a whirlwind"—further, that (in words which remind us of the celebrated Macpherson) "he was by no means an ordinary person". The Recluse of the Western Brook continues: "conversation with him showed me that his learning was tremendous; there seemed to be no book he had not read". In spite of his age, when Chingiz Khan's call for the long double journey came to him at Lai-chou from far-off Afghanistan,

> "here was the Master setting out to cover thousands of miles of most difficult country, through regions never mapped, across deserts unwatered by rain or dew, in which, though he was received everywhere with the utmost honour, it was inevitable that he should suffer considerable hardship and fatigue. Yet whenever opportunity arose he was ready to loiter on the way, enjoy the beauties of the scenery in the most natural and leisurely manner, write a poem, talk or laugh."

Ch'ang-Ch'un arrived at Samarkand early in December 1221, and wintered there. When he reached Chingiz's camp, between the Hindukush and Kabul, in the following May, "Chingiz was delighted, begged him to be seated and ordered food to be served. Then he asked him: 'Adept, what Medicine of Long Life have you brought me from afar?' The Master replied: 'I have means of protecting life, but no elixir that will prolong it.' The Emperor was pleased with his candour, and had two tents for the Master and his disciples set up to the east of his own." The central incident of the narrative thus has a bearing upon the alchemical doctrine of the elixir of life. "A temporary compound of the Four Elements," says Ch'ang'-Ch'un in another place, "the body at last must suffer decay. The soul, composed of one spiritual essence, is free to move wherever it will."

More direct than the alchemical references are those to astronomy and astrology. At Talas, near the modern Aulie-ata, notice was taken of "a number of great mounds, set like the stars in the Polar Constellation". At Samarkand, the Master held a conversation with an astronomer about a recent eclipse of the sun.

---

* Reference may be made here to Mr. Waley's "Notes on Chinese Alchemy" (supplementary to O. S. Johnson's "A Study of Chinese Alchemy") in the *Bulletin* of the School of Oriental Studies, London Institution, vol. 6, part 1, 1930.

"The man said: 'Here the eclipse was at its full at the hour of the Dragon, when it covered three-fifths of the sun.' 'We were by the Kerulen River,' said the Master; 'the eclipse was total towards mid-day. But when we came south-west to the Chin Shan, the people there said that at the hour of the Snake it reached its greatest extent, covering seven-tenths. Thus in three places it was seen in three different ways. K'ung Ying-ta [574–648 A.D.], in his commentary on the *Springs and Autumns*, says that when the moon comes between us and the sun there is an eclipse of the sun. In the present case only those who were in a direct line with the sun and moon experienced a total eclipse. By those away from this line the eclipse is seen differently, the gradual change becoming considerable at a distance of a thousand *li*. It is just as though one covered a candle with a fan. In the direct shadow of the fan there is no light, but the further one moves to the side the greater the light becomes.'"

Mr. Waley explains that the Chinese believed that every point on earth was influenced by a corresponding point in the heavens. Thus, on a certain day the Controller Wang Chi appealed to the Master to avert the danger threatening the district of Pekin through the impinging of the planet Mars upon the constellation Wei. The Master hurriedly arranged a service, and upon the second night "the planet was now several mansions away . . . so swiftly had the Master's magic taken effect. . . . A large number of Taoists came from distant places with offerings of chrysanthemum-flowers. He made for them a poem in lines of unequal length, to the tune *Yü Shêng Hên Huan Ch'ih*."

Many incidents are related which bring out traits in the Master's character. The governor of Samarkand gave a banquet in his honour. "Noticing that the Master drank very little, he begged to be allowed to press a hundred pounds of grapes and make him some new wine. But the Master answered: 'I do not need wine. But let me have the hundred pounds of grapes; they will enable me to entertain my visitors.'" Upon another occasion, stories were related of mischievous mountain spirits which had cut off the back hair and departed with the choicest provisions of the narrators. "The Master made no comment on these stories."

Among his varied accomplishments, the Master was skilled at rain-making and poetry. During the great drought of 1227, the authorities offered up prayers in vain.

"The Taoist congregations in the City came one day and begged the Master to perform the rain-bringing service. . . . The Master said quietly: 'I was just thinking of celebrating such a service. That you, sirs, should have come with the same suggestion is an example of what is called "spontaneous identity of ideas". There remains nothing for it but that you . . . should devote all your energy to the arrangements.' . . . And sure enough as the time for the service arrived, rain fell all day, and by next day a foot of it had fallen."

Upon occasion, the Master applied his poems with great effect.

"One day there was a dispute and the Master was asked which side he took. He remained silent, and thus settled the question in accordance with the spirit of Tao. Presently he gave them the following hymn:

Sweep, sweep, sweep!
Sweep clear the heart till there is nothing left.
He with a heart that is clean-swept is called a 'good man'.
A 'good man' is all that is meant by 'holy *hsien*' or '*Fo*'.

The disputants retired discomfited."

The narrative abounds in pleasant reading of this kind, and at the end our old Chinese alchemist leaves us to exclaim with bully Bottom: "I desire your more acquaintance, good Master!"

JOHN READ.

The New Crystallography.

Strukturbericht, 1913–1928. Von P. P. Ewald und C. Hermann. *Zeitschrift für Kristallographie, Kristallgeometrie, Kristallphysik, Kristallchemie*, Ergänzungsband. Pp. iv + 818. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1931.) 47 gold marks.

THE publication in book form of the reviews which have been appearing for several years in the *Zeitschrift für Krystallographie* will be warmly welcomed by those interested in the structure of crystals. The book contains a survey of all work in this field from 1913, when the first analyses by X-ray methods were made, to the end of 1928. The older crystallography was mainly concerned with the external form and physical properties of crystals; its achievements are recorded in the five volumes of Groth's "Chemische Krystallographie". The present volume makes a first step towards fulfilling the same function in the new field as Groth's monumental work in the old, and we owe a great debt to the authors for the immense amount of labour which must have been put into its compilation. Their task has been no easy one. Not only is the output of papers increasingly great every year, but also it is often difficult to sort the wheat from the chaff, and estimate from an author's account the reliance to be placed on his conclusions.

The new crystallography probes more deeply, and attempts to give the arrangement of atoms in the structures. The centre of interest has shifted, and the external crystalline form, which has for long been the chief preoccupation of crystallography as a means of classification and examination, is now to be reckoned as a secondary and relatively unimportant manifestation of the underlying structure, dependent on elusive factors, and telling little about the crystal. The less ambitious aim of the investigations into crystalline form gave a precision and completeness to the results, and Groth was able to condense the data into a single account for each crystal. The new field is only partially explored; early results are continually being modified and new crystals investigated. Hence the authors of the "Strukturbericht" have both classified, when possible, and also given summaries of all the individual papers in a form which is very convenient to consult.

The crystals are divided into the classes of elements and inorganic compounds, alloys, and organic compounds, and each class is subdivided into groups of types. For example, the elements are classified under the types *A*1 (face-centred cubic lattice), *A*2 (body-centred cubic lattice), *A*3 (hexagonal closest packing), and so forth. Compounds with formula *AB* belong to *B* types, those with formula AB_2 to *C* types. The descriptions of the types are very clear, and figures are numerous and cleverly drawn so as to give an appearance of perspective. A separate diagram shows the way in which each atom is surrounded by neighbours. After the description of the type, a detailed list of crystals belonging to it is given, with tables of parameters and interatomic distances. Then, at the end of the descriptions of types in each group, all relevant papers are briefly reviewed, the writers' conclusions being summarised and in some cases a critical paragraph added.

The description of the salient physical features of each structure is a model of completeness and conciseness, and is often a great improvement on the account in the original papers. The value of all the information in the "Raumgruppentabelle", which lists the purely geometrical properties of symmetry of each structure, is not so apparent. To take an example, the structure of indium is based on a tetragonal space-lattice. A list of 35 space groups is given, of each of which the indium lattice may be regarded as a special case, and the corresponding atomic symmetry, "Hauptinseln" and "Minimum Inselsymmetrie" are faithfully recorded for each group. Not only is it doubtful whether such data have a physical significance or correspond to any property of the constituent atoms, but also, in the unlikely contingency that these symmetry properties are required, they can be readily seen from a glance at the structure.

The division into types is convenient in the case of the simple inorganic compounds and alloys, where many compounds containing different elements crystallise in a similar way. It is not so well suited to the organic compounds. Here one is dealing with a variety of structures in which the elements are the same, and there are practically as many types as compounds. Possibly a different method of classifying these structures will finally be adopted.

An excellent feature of the book is its indexing. There are four indexes, for authors, names of compounds, formulæ, and types; it is easy to find any information one requires. The whole book is very successfully planned. The authors must be congratulated, both for their courage in tackling such a heroic task and for their skill in devising a scheme which is so sound and so easily extended to embrace new knowledge, and on which future reviews will no doubt be modelled.

W. L. BRAGG.

Science in the Rabbit Industry.

The Scientific Aspects of Rabbit Breeding. By James N. Pickard and F. A. E. Crew. Pp. ix + 122 + 12 plates (Idle, Bradford; and London: Watmoughs, Ltd., 1931.) 6*s.* 6*d.*

THIS little book affords welcome evidence of an increasing inclination on the part of the animal breeder to turn to science for guidance. For its publishers are also the publishers of the principal weekly paper dealing with the rabbit industry and fancy, and they must have scented an opening for such a work. Indeed, it is fully time that such a work appeared, for the cult of the rabbit has undergone profound changes since the War. Twenty years ago the only breeders of rabbits who mattered were the fanciers, and it was almost entirely for them that the literature catered. As compared with to-day, relatively few varieties were standardised, the object of breeding being solely for show purposes. Rabbit keeping was a hobby, and though from time to time enthusiasts would suggest the possibility of industrial exploitation, yet the author of "The Book of the Rabbit", writing in 1889, stated that "as against all theories to the contrary, the stern fact remains that a

BOOK NO........
LIBRARY

modern instance of profitable rabbit farming is unknown".

It was only with the War that the rabbit began to come into its own. Thousands then realised that it was easy to keep and not too disagreeable to eat. Even so, the advent of peace, bearing cheap beef and mutton, might have led to renewed stagnation in the rabbit world had not another circumstance reacted in its favour. The general raising of the standard of life led to a greatly increased demand for inexpensive furs such as the rabbit alone could supply. Fortunately also, the rabbit had 'sported' several attractive new colours during the earlier part of the century, and these were available when the fur boom started. With good skins fetching up to 10*s*. apiece, and even more, rabbit farming at once became a profitable industry. Though, like other industries, it has suffered recently from the prevailing depression, there are sound reasons for expecting it to flourish once more when the general outlook brightens.

In the first place, it is clear that 'wild' furs must become progressively less able to cope with the world demand, with the consequent advantage to the pelt of the rabbit. Secondly, the new 'sports' in colour and texture of fur which have appeared during the past few years have added enormously to the variety of *natural* rabbit furs. In earlier days the choice was very limited, and rabbit pelts were generally dyed to render them more attractive. This naturally affected their durability, so that rabbit fur got a bad name, which it has not yet lived down. This prejudice must eventually pass away, for the natural fur, pelted at the right time and properly treated, lacks nothing in durability.

At present one of the obstacles to the spread of the new types of fur is the difficulty of producing a uniform article in sufficient quantities, and it is here that the breeder is beginning to make use of modern genetical knowledge. These new types are largely the result of recombinations through crossing, and in the hands of the ordinary breeder throw many unwanted forms, with consequent loss. This, of course, could be avoided if the breeder were to work in the light of what is already known about the genetics of the rabbit, and it is with the idea of assisting him that the present little book has been brought out.

No more competent guides could have been selected either from the point of view of scientific attainment or of practical experience. They have produced between them an excellent little treatise which covers the whole ground of the physiology, nutrition, genetics, and general management of the animal. The genetical part, as might be expected, is fully entered into, and an analysis in terms of genetical factors is given for all the principal breeds. At the same time, the breeder is initiated into the modern manner of recombining characters, and of the steps necessary to form them into fixed breeds with the least expenditure of time and energy.

The chapters on nutrition and management are eminently practical, and, though mainly devised for the industry, the book should prove of great service to all who make use of the rabbit for scientific purposes. It concludes with a serviceable bibliography.

Short Reviews.

(1) *Outlines of Physical Geology.* Prepared from the Third Edition of Part I. of Pirsson and Schuchert's "Textbook of Geology" by Prof. Chester R. Longwell. Pp. vi + 376. 1930. 15*s*. net.
(2) *Outlines of Historical Geology.* By Prof. Charles Schuchert. Second edition, rewritten. Pp. v + 348. 1931. 15*s*. net.
(New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd.)

(1) THE first of these "Pirsson-Schuchert Geologies" is a shorter form of the 1929 revision of Pirsson's "Physical Geology" (NATURE, Oct. 4, 1930, p. 531) made by members of the Yale Department of Geology under the editorship of Prof. Longwell. The chapters dealing with the interior of the earth, ore deposits, and land forms have been omitted from this abridgment, and all the remaining chapters, except Chap. i., have been shortened. The book is authoritative and beautifully illustrated and can be confidently recommended to elementary students of geology and physical geography. The prospective buyer, however, would be well advised to pay the extra 3*s*. 6*d*. and acquire the more complete revision of 1929.

(2) Prof. Schuchert's "Outlines" is in its origin an abridgment of his much longer "Historical Geology" of 1924 (NATURE, Sept. 13, 1924, p. 376), but in its present dress it constitutes practically a new book. It gives an admirable summary of "the archives of life's adventures". The continuity of the historical story is now less broken into by sections dealing with plants and animals, as the latter have been brought together to form two of the introductory chapters. More stress has been laid on evolution as the keynote of geological chronology and correlation. Considerably more attention has also been given to palæogeography, and the maps for which Prof. Schuchert is justly famous have been redrawn in accordance with the additional data now available. The book is more richly adorned with splendid illustrations than any other comparable work. Both students and teachers and also the ordinary reader who may be looking for a coherent account of the principles of earth history

will be amply rewarded by Prof. Schuchert's competent management of his vast subject.

We are informed by the publishers that the two works are now available as a single volume entitled "Foundations of Geology", price 25*s*. net.

Climatology. By A. Austin Miller. (Methuen's Advanced Geographies.) Pp. x + 304. (London: Methuen and Co., Ltd., 1931.) 12*s*. 6*d*. net.

THIS is an excellent book, well produced and well illustrated, and should be of great value to geographers both for reading and reference. After three introductory chapters on the scope of climatology, the elements, and the factors of climate, the major part of the book is descriptive. The author first sets out the modern ideas on the classification of climates, especially those of Köppen, and then arranges his material according to the major climatic provinces—equatorial, tropical, tropical monsoon, etc., ending with two chapters on desert and mountain climates. This logical arrangement is probably the best for teaching purposes, though it breaks up the unity of the continents. The various climatic types and subtypes receive clear treatment, illustrated by charts and diagrams, and completed by paragraphs on the associated vegetation and cultivation; and each chapter is followed by a short bibliography and by two pages giving averages of temperature and rainfall for a number of typical stations. The book ends with an interesting chapter on changes of climate, and a very good index.

The author's physical explanations are sometimes obscure: thus, a cooling breeze surely cannot promote radiation, as stated on p. 13, though it does promote conduction; and the explanation of the vertical decrease of temperature on p. 37 is very muddled. The diagram on p. 184 is also difficult to understand; the fact that the "highest mean monthly maximum on record" (whatever that is) at Cambridge in January is just higher than the "lowest mean monthly minimum on record" in July is not evidence that "the coldest July was actually colder than the warmest January", a statement which is, in fact, incorrect. These are small blemishes, however, and the book as a whole shows that the author has read with understanding as well as widely.

Commonwealth Bureau of Census and Statistics, Canberra. Official Year Book of the Commonwealth of Australia. No. 23, 1930. Prepared under instructions from the Minister of State for Home Affairs by Chas. H. Wickens. Editor: John Stonham. Pp. xxxii + 806. (Melbourne: H. J. Green, 1931.) 5*s*.

THE issue of this year book for 1930 is considerably smaller than for recent years, and yet a comparison with last year's volume suggests that nothing of real importance has been omitted. As usual, the book contains full statistics of every aspect of Australian activity, and, in many cases, the figures for recent years which enable comparisons to be made.

It has been the custom for the Year Book to contain at least one specially contributed article. This practice is continued with an article by Prof. Radcliffe Brown on the former numbers and distribution of the Australian aborigines. In making his estimates, for which data naturally vary in different parts, Prof. Brown has divided each State into districts which so far as possible are those recognised by the natives. The final figures give 251,000 as the lowest, and 300,000 as the highest, figure for the original population of Australia. This is equal to 12 per square mile for the continent as a whole with as many as 38 per square mile in South Australia and as few as 6·7 per square mile in Queensland. Prof. Brown admits that much of the evidence on which these figures are based, especially in regard to Queensland, New South Wales, and Tasmania, is not wholly satisfactory.

The Journal of the Institute of Metals. Vol. 44. Edited by G. Shaw Scott. Pp. xii + 880 + 56 plates. (London: Institute of Metals, 1930.) 31*s*. 6*d*. net.

THIS volume is the last of the present series. In future, the papers read before the Institute of Metals will appear, as before, in half-yearly volumes, but the abstracts will form a third volume, published annually. The papers read at the Southampton meeting include several on aluminium alloys, including an illuminating discussion of the methods of refining the grain size of aluminium by the use of volatile chlorides or of chlorine-bearing vapours. It appears that the entry of water vapour from products of combustion into aluminium and its alloys may be particularly harmful. An interesting monograph on the origin and development of rolled gold contains information which will be new to most readers, on a material in familiar use. Further work has been done on the atmospheric corrosion of copper, and a basic sulphate is shown to be the principal constituent of the product in ordinary atmospheres, largely replaced by the basic chloride in marine situations. Prof. Tammann has contributed a paper on the determination of crystallite orientation in metals, which will be found useful as a summary of numerous papers by that author which have appeared elsewhere. The plates are, as usual, excellently produced.

Exercices de mécanique. Par H. Beghin and Prof. G. Julia. Tome 1, Fascicule 2. Pp. iv + 337-577. (Paris: Gauthier-Villars et Cie, 1931.) 60 francs.

THIS part of the work, by M. Beghin and Prof. Julia of the Faculty of Science of the University of Paris, contains six chapters dealing with fundamental laws, general theorems, work and power, virtual work, impulsive motion, and Lagrange's equations as applied to this type of motion. Each chapter contains a short theoretical introduction and a collection of illustrative examples worked out in detail. These are usually of a fairly advanced type, and frequently deal with interesting physical or engineering problems. The book should be useful to the teacher in search of problems or to the student working alone from text-books.

Science in the City of London.

By Engr.-Capt. Edgar C. Smith, O.B.E., R.N.

To the student of the history of science and technology London offers a field of inquiry of wide and unfailing interest. From Westminster Abbey to the docks, from Highgate to Clapham, all routes lead to some spot with scientific associations. Ever since the Romans came, bringing with them their measuring, surveying, and surgical instruments, London has owed something to scientific inquiry, and the construction of her gates and fortifications, her historic Bridge, and her great Tower were only rendered possible through the discoveries of the ancient world. But great as is our debt to Greece and Rome, it is within modern times that science has invaded every side of human activity, and many of the most important discoveries, many of the most notable inventions, and many of the most striking applications of science have been made in London. Thus it is that from one boundary of London to the other her streets and lanes, her institutions, hospitals, and workshops, her cathedrals and churches, the river and its bridges, her parks and gardens, all have some tale to tell relating to the increase of natural knowledge.

Obvious as are the many applications of science to practical affairs to-day, and numerous as are the records of men of science who have lived and worked in London, the annals of science in the City of London still remain fragmentary and scattered. The intrinsic interest in the story was well shown by Mr. H. G. Wayling in his articles on "The Romance of Science in Bygone London", published in *Science Progress* in January and April this year, and also in Dr. Charles Singer's address on "The First Century of Science in England", given during the recent International Congress of the History of Science and Technology. The subject, too, is happily claiming the attention of the British Association, which this year for the first time is meeting in London.

"The general attitude to Nature", said Dr. Singer, "which we nowadays call scientific was opened, as far as England was concerned, by the appearance of certain works of Giordano Bruno." These works were surreptitiously printed in London in 1584, probably in the Charterhouse. Fourteen years before that, however, Henry Billingsley, Sheriff of London in 1584 and Lord Mayor in 1596, had published the first English translation of Euclid. With "a very fruitfull Præface" by Dee, Billingsley's book was printed by John Daye, dwelling over Aldersgate beneath Saint Martins. Billingsley became a knight and a member of parliament, and died in 1606. If to him we are indebted for the earliest English translation of the "Elements of Geometry", to his famous contemporary Sir Thomas Gresham we owe the establishment of Gresham College and the founding of the earliest chairs of geometry and astronomy in the country. Some science had been taught at Oxford and Cambridge long before then, but the foundation of Gresham College was one of the most important steps taken in connexion with the educational facilities of London, and with its history the story of modern science in London rightly begins.

Gresham was born about 1519 and died in 1579. The son of a Lord Mayor, he was a servant of the State as well as a great merchant, and, during the reigns of Edward VI., Mary, and Elizabeth, acted as a sort of financial ambassador. In 1566 he founded the Royal Exchange, and, perhaps influenced by the establishment in Paris by Francis I. of the Collège Royale, now the Collège de France, he left his fine mansion in Bishopsgate to the London Corporation and the Mercers' Company for a college and endowed chairs in physic, geometry, astronomy, music, law, rhetoric, and divinity. His widow dying in 1596, the bequest then became available and the first lecturers were appointed. Briggs was chosen first professor of geometry and Brerewood first professor of astronomy. To them succeeded in turn Edmund Gunter, the inventor of Gunter's chain; Henry Gellibrand, who completed Brigg's "Trigonometria Britannica"; John Greaves, the first man in modern times to measure the Pyramids; Samuel Foster, the author of "The Use of the Quadrant"; Rooke, declared to be "the greatest man in England for profound learning"; Walter Pope, a contributor to the first volume of the *Philosophical Transactions*; and Barrow, Wren, and Hooke. Some of these, it will be recalled, were among the founders of the Royal Society, which from its foundation in 1660 until 1710, except for a few years after the Great Fire, met in Gresham College.

In the seventeenth century, London was also the home of Thomas Harriot, the algebraist and the first Englishman to observe sunspots; Walter Warner, Thomas Allen, Nathaniel Torporley, who is said to have acted as amanuensis to Vieta, and Dr. Wilkins, who "deserves more than any man to be esteemed the founder of the Royal Society". Many of these scientific worthies were buried in the City churches, although to-day, owing to the destruction by the Great Fire and to other causes, one may look in vain for memorials of them. Billingsley was buried in St. Katherine Coleman, Fenchurch Street; Brerewood and Hooke, like Gresham himself, in St. Helen's, Bishopsgate, "the Westminster Abbey of the City"; Gunter, Foster, and Gellibrand in St. Peter the Poor in Broad Street; Torporley in St. Alphage in London Wall; Rooke in St. Mary Outwich, Bishopsgate; Pope in St. Giles', Cripplegate; Harriot in St. Christopher le Stocks, a church which had to make way for the Bank of England; Greaves in St. Benet's, and Wilkins in St. Lawrence Jewry, of which he was one time rector. Of other old mathematicians, Thomas Digges was buried in St Mary Aldermanbury; and Collins, "the attorney-general for the mathematics", in St. James', Garlick Hill. Wren, of course, lies in St. Paul's; and Barrow in Westminster Abbey.

Bishopsgate, besides being the street in which Gresham College was situated, is the centre of a district abounding in scientific interest. In Winchester Street hard by, at his father's house, Halley, as a boy of nineteen, began his astronomical observations; in Austin Friars, Aubert had the first of his three observatories; and at the offices of the Magnetic Company, in Old Broad Street, in 1856, the electricians, Whitehouse and Bright, showed Morse that signals could be sent at the rate of 272 a minute through 2000 miles of wire laid to and fro between London and Manchester. Latimer Clark had shown Airy and Faraday the same experiment at Lothbury in the City three years before. In Bishopsgate also stands the little church of St. Ethelburga, which has recently been enriched with three beautiful windows erected to the memory of Henry Hudson, who with his crew took Holy Communion in the church on April 19, 1607, the day before he set sail in the *Hopewell*, Frobisher's old ship. Then, too, Birchin Lane and Finch Lane, at the back of the Royal Exchange, remind us of the work of Newcomen and Watt. For a year, Watt worked in Finch Lane learning to make sextants, all the time going in fear of the press gang. Farther to the east, the Tower, the Mint, and Trinity House all have links with modern science; with one or the other have been connected Sir Jonas Moore, Flamsteed; Drummond, the inventor of the lime-light; Forsyth, the inventor of the fuse; Newton; Graham the chemist; Sir John Herschel; Roberts-Austen, who was responsible for the quality of no less than £150,000,000 of gold coins; the engineers Barlow and Douglas; and Faraday, Tyndall, and Rayleigh. The City, too, was the home of the early clock makers, map makers, and instrument makers, and some of these were associated with the old Mathematical Society of Spitalfields, of which Major P. A. MacMahon gave some particulars in his presidential address to Section A of the British Association in 1901.

This old scientific society came to an end in 1845, but long before then the centre of London science had shifted westward. Just as the history of science in London in the seventeenth century is bound up principally with the district to the east of St. Paul's, so its history in the eighteenth century brings us to the west of St. Paul's and to Fleet Street and the Strand. St. Paul's itself, as Mr. Wayling has pointed out, Christ's Hospital, the Charterhouse, Child's Coffee House in St. Paul's Churchyard, the London Coffee House in Ludgate Hill, the Mitre Tavern in Fleet Street, and the Crown and Anchor in the Strand, all have some scientific associations, as also have the Temple and Somerset House.

Fleet Street abounds in both literary and scientific associations, and to-day the Newcomen Society frequently meets in Prince Henry's Room in a house which was familiar to Newton and his fellows who came to Crane Court in Fleet Street for the meetings of the Royal Society. On Sept. 8, 1710, Newton as president had summoned the council of the Society for the purpose of informing them that the house of the late Dr. Brown in Crane Court was to be sold, " and being in the middle of the Town, and out of noise, might be a proper place to be purchased by the Society for their Meetings ". The outcome of this suggestion was the purchase for £1450 of Dr. Brown's house and the next; and on Nov. 8, 1710, the Society held its first meeting in its own home, and Gresham College, much to its detriment, saw the Society no more. During the seventy years the Society met at Crane Court it had ten different presidents, among whom were Sir Hans Sloane, Martin Folkes, Sir John Pringle, and Sir Joseph Banks, the last of whom was just beginning his long period of office, when in 1780 the Society, through George III., was granted the use of apartments in Somerset House. Newton's last appearance in Crane Court was when he presided over a meeting on March 2, 1727, eighteen days before he died. To the period the Society was housed in Crane Court belong the labours of Halley, Bradley, and Hadley; the foundation of the Copley Medal and its award to Gray, Desaguliers, Bradley, Harrison, Canton, Franklin, Dollond, Smeaton, Cavendish, Priestley, and Cook; the promotion by the Society of the practice of inoculation; the controversy over lightning conductors, and the furtherance of expeditions to observe the transits of Venus of 1761 and 1769.

In those days several members lived quite close to Crane Court. James Ferguson, elected F.R.S. in 1763, a very remarkable self-taught man, had his home in Bolt Court, where Johnson lived, and he died there in 1776. From Ferguson's books Herschel gained his first knowledge of astronomy. Crane Court and Bolt Court are on the north side of Fleet Street. On the other side was Water Lane, now Whitefriars Street. Tompion, the famous watchmaker, had a shop at the sign of the Dial and Three Crowns at the corner of Water Lane. Here George Graham worked for Tompion, married his niece, and succeeded to his business, which, however, he moved across Water Lane to the Dial and One Crown. Graham's house was a workshop, a laboratory, and an observatory combined. He and Tompion to-day rest in the same grave in the nave of Westminster Abbey. Another famous Fleet Street instrument maker was Pinchbeck, and another, Troughton, who died at No. 138. Just below Whitefriars Street is Salisbury Court, leading to St. Bride's Church and Dorset Street. Salisbury Court once contained the " workhouse " of Captain Thomas Savery, " the most prolific inventor of his day ", and there in 1702 his steam pumps could be seen.

In St. Bride's Church is the monument to Dr. Wells, bearing representations of the Rumford Medal of the Royal Society, which was awarded him for his excellent memoir on dew. The church also recalls the names of Wren and of the chemist Delaval, who described the damage done to it by lightning in 1764. He also wrote an account of the damage to St. Paul's by lightning in 1772. About forty years after this, at No. 53 Dorset Street, lived Mr. Tatum, in whose house the City Philosophical Society met on Wednesday evenings.

After his trip to the continent with Davy, Faraday became a member of this Society and it was in this house he served his apprenticeship as a lecturer.

Such are a few of the scientific associations of Fleet Street and its neighbourhood. Were it possible to continue the story, the survey would take us into Chancery Lane and Gunpowder Alley and to the Middle Temple, where William Ball, the first treasurer, was buried, and Garden Court, the first home of the Geological Society, and thence back into the Strand and its surroundings, and so still farther westward. For the history of science in both the City of London and greater London during the nineteenth century, the birth and growth of our great scientific and technical societies and institutions, their work and influence, as well as university education, the volume on "London and the Advancement of Science", published by the British Association, should be consulted.

Altogether apart from the records of any organisation, however, there is much of an intimate and personal character awaiting the student of science in London. In the lives of men of science, as in the lives of others, are to be found those incidents, anecdotes, and observations which are the breath of biography and by which we are able in some degree to reconstruct the past. With a knowledge of the past, London becomes a place of memories, and in imagination we can join the company of Raleigh and the Earl of Northumberland and his 'three magi' in the Tower, or visit the lecture rooms of Hauksbee and Desaguliers or stand beside Voltaire at the grave of Newton. In fancy we can endeavour to break through the strange seclusion in which Cavendish lived and worked in his house on Clapham Common, watch Davy in the laboratory overcome with delight as he sees the first globules of metallic potassium form, assist Frank Buckland in his efforts to find the coffin of John Hunter in the crypt of St. Martin's-in-the-Fields, or travel across London with Kekulé on the evening he first saw the atoms linked.

This story is best told in Kekulé's own words. It takes us back to 1855, when Kekulé, at the age of twenty-six, was assistant to Stenhouse at St. Bartholomew's Hospital. Living in Clapham, he was returning home from a visit to Hugo Müller at Islington. "One fine summer evening", he says, "I was returning by the last omnibus, 'outside' as usual, through the deserted streets of the metropolis, which are at other times so full of life. I fell into a reverie, and lo, the atoms were gambolling before my eyes! Whenever, hitherto, these diminutive beings had appeared to me, they had always been in motion, but up to that time I had never been able to discern the nature of their motion. Now, however, I saw how frequently two smaller atoms united to form a pair; how a larger one embraced the smaller ones; how still larger ones kept hold of three or even four of the smaller; whilst the whole kept whirling in a giddy dance. I saw how the larger ones formed a chain dragging the smaller ones after them, but only at the ends of the chain. I saw what our Past Master, Kopp, my highly honoured teacher and friend, has depicted with such charm in his 'Molekularwelt'; but I saw it long before him. The cry of the conductor, 'Clapham Road', awakened me from my dreaming; but I spent a part of the night in putting on paper at least sketches of these dream forms. This was the origin of the Structurtheorie."

Modern Apparatus for the Reproduction of Speech and Music.

By Dr. N. W. McLachlan.

Sounds can be divided broadly into two classes: (*a*) transients, with which one is mainly concerned in speech, and to a lesser extent in music; (*b*) continuous sounds, which pertain chiefly to instrumental music and singing. Since a transient can be represented by an infinite frequency spectrum, the ideal apparatus should be capable of reproducing the entire range from zero to infinity. Fortunately for designers, the sensitivity of the ear is limited to the range 25-20,000 cycles (according to the individual). The widest range adequately covered by a single reproducer is from 50 to 7000 cycles, but this can be extended to 12,000 cycles by an additional reproducer. The range covered by the ordinary domestic loud speaker of the moving coil variety is roughly from 40 to 5000 cycles.

The energy of speech and music is conveyed by the frequency band below 500 cycles, whilst the interpretational and intelligibility characteristics reside in the range above this. Attenuation of the lower register is accompanied by a lack of body; for example, a pedal organ sounds like a harmonium. Attenuation of the upper register makes speech woolly, unnatural, and difficult to understand, music loses character and brilliance, whilst transients are travestied to a new type of sound; for example, the *rustle* of paper has never been heard over the microphone! The faithful reproduction of paper rustling and coin jingling involves frequencies greater than 10,000 cycles.

It is impossible to deal here with all forms of reproducing apparatus, but two representative types have been chosen, in both of which the driving mechanism is a circular coil immersed in a strong radial magnetic field. In the first or hornless type, the reproducing mechanism is a conical paper diaphragm 10-15 cm. in radius, to which the coil is rigidly attached (Fig. 1). The coil is constrained to move axially by a centering device, whilst the diaphragm is supported at its periphery by an annulus of leather, rubber, or other material. This arrangement is associated with some form of baffle to prevent interference between the pressure waves on each side of the diaphragm, since they are of opposite sign. The interference increases with the wave-length and is, therefore, greatest at low frequencies. To prevent appreciable reduction in output at, say, 100 cycles, the distance from centre to centre round the baffle should be half the wave-length, which makes the baffle about six feet round or square. In commercial apparatus for domestic purposes these dimensions are not realised. It is customary to use a cabinet which often introduces resonance effects. For talking pictures, however, a baffle is generally used.

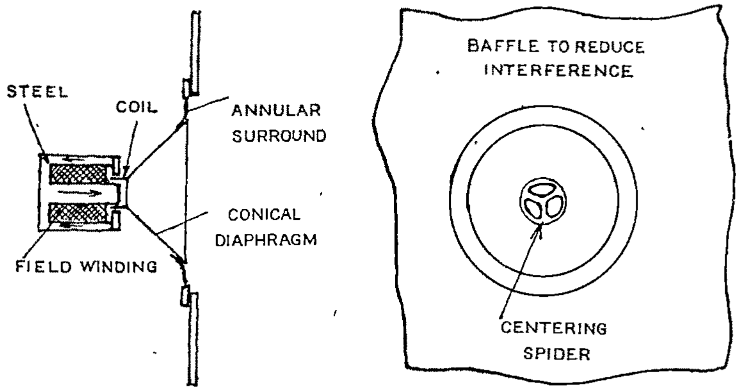

FIG. 1.

In the second type of reproducer, the diaphragm is within the coil and is used in conjunction with a horn, the cross-section of which increases exponentially (Fig. 2). The low frequency cut-off of the horn depends upon the rate of expansion and upon the length. A long horn permits a gradual expansion, whilst the diameter at the open end can then be greater than a quarter of the wave-length of the lowest frequency to be adequately reproduced. These conditions are concomitant with small reflection within the horn, whilst at the mouth the reflection is only serious for those frequencies below the cut-off point. For adequate reproduction below 100 cycles per second, an axial length of 15-25 ft. is required.

The coil and diaphragm (Fig. 2) is attached to a flexible annulus, the outer edge being securely clamped to the electromagnet. The natural frequency of the system on open circuit *in vacuo* is 400 cycles per second. The diaphragm is shaped to give rigidity, so that it moves substantially as a whole over a wide frequency band. The obstruction *H*, apart from reducing the throat area and thereby increasing the air particle velocity, acts as a phase equaliser. The clearance between the diaphragm and *H* gradually increases with the radius. Thus, during vibration the velocity of the air particles most remote from the horn aperture is increased, so that up to quite high frequencies the pressure from all parts of the diaphragm arrives in the main column in substantially the same phase.

In the early days of broadcasting it was thought that the ideal diaphragm (10-15 cm. radius) ought to move as a whole. Some years ago I showed that, owing to interference, the power output above 1000 cycles decreases so rapidly that a rigid structure would be of no value for modern moving-coil loud speakers using a baffle. After the 'moving coil' made its début, it was believed in certain quarters that the diaphragm moved as a whole over a wide frequency range. When the apex or the coil is tapped, a complex sound corresponding to the natural frequencies of the diaphragm is heard, whilst during operation the output above 1000 cycles usually exceeds that at lower frequencies. Such effects preclude the possibility of rigidity throughout the acoustic register.

I have shown recently that the action of a moving coil loud speaker depends upon resonances throughout the frequency range. The lower register is due to resonance of the annular support, acting as an auxiliary diaphragm, or to resonance of the diaphragm as a whole on the support or on the centering device of the coil. The upper register is due to the centre moving symmetrical modes of the diaphragm. If the low frequency resonances are eliminated, the upper register is overpowering and the reproduction lacks body. Owing to transmission loss in the diaphragm and to interference in the surrounding space, there is an upper frequency cut-off and considerable attenuation occurs above 5000 cycles.

FIG. 2.

The reaction on the driving coil consists of two components in quadrature: (*a*) resistive due to the radiation of sound and transmission loss; (*b*) reactive due to the mass of the diaphragm including the accession to inertia caused by divergence of sound waves from the diaphragm as source. The mass reactance is a considerable proportion of the total mechanical impedance and reduces the amplitude of vibration considerably unless it is offset by elasticity of the diaphragm structure.

As in the case of a heat engine, the efficiency of an electrical-mechanical-acoustical apparatus can be stated in several ways. For the present we shall take the ratio η = acoustic output/electrical input. The value of η depends upon the magnitude of the resonances and the strength of the magnetic field. For a hornless type driven by a coil 2·5 cm. radius, 0·95 cm. long, and a radial field strength of $1 \cdot 3 \times 10^5$ lines per sq. cm., an efficiency of 10 per cent or more can be obtained over a certain frequency range.[*] By using a stronger field the efficiency can be increased. Where a permanent magnet is used, as in apparatus for domestic use, the efficiency is more likely to lie between 2 and 4 per cent.

When a horn is used, the radius of the diaphragm is usually about 2·5 cm. As in the preceding case, the reaction on the coil can be divided into resistive and reactive components. By means of the horn, however, the resistive component can be made relatively larger than in the hornless type of reproducer.

The horn acts as a coupling device which enables the high-pressure low-volume energy in the immediate vicinity of the diaphragm (the coupling chamber) to be transformed gradually and efficiently into low-pressure energy ultimately supplied to a large volume of air. This is very different from the large diaphragm type, where no attempt at impedance matching is made. The resistive load being relatively higher than in the hornless reproducer, means that the efficiency is correspondingly larger, whilst resonances are more heavily damped. Efficiencies of 30 per cent over a wide range can be obtained with a horn 15-25 ft. in axial length. Consequently, these instruments are invaluable for public address and entertainment purposes where an acoustic output of several watts is required.

With the same input, the reproduction of broadcasting by aid of a well-designed horn apparatus[†] is louder and better than that from a large diaphragm apparatus using a baffle. Although the lower register is more powerful in the latter case, the resonances are more marked and more sustained,[‡] whilst the upper frequencies are weaker. Moreover, the reproduction of transients is better with the horn type.

The operation of loud speakers for public address and entertainment purposes where the acoustic output runs into watts, requires a power installation. From a supply engineer's point of view the power is negligible, but in comparison with that required for domestic receivers it is large. In speech and music, peak values ten or more times the mean value occur in transients. To avoid distortion, it is essential that on the average the output valves are not worked to their limit. This necessitates applied voltages of from 500 to 1000.

In receivers for domestic purposes, it is seldom that the voltage applied to the valves exceeds 220. This combined with reproducers of low efficiency often means that in an attempt to get adequate volume, the output or power valve is worked beyond its normal capacity. On loud passages considerable distortion ensues, due to the creation of alien frequencies arising from operation beyond the linear limits of the valve characteristics. For undistorted output the general loudness level must be fairly low. Although this meets with approval in many households, it must be realised that with music it is desirable to have a reasonable loudness level, to simulate conditions in the concert hall or studio. The effect of loudness level is related to the physiological properties of the ear. If we listen close to a band in the park, the fundamental tones of all the instruments, from the bass drum upwards, are in evidence. But when we walk slowly away from the band, the pitch of the lower-toned instruments appears to alter, and ultimately the music sounds thin. This is due to the insensitivity of the ear to low frequencies. Beyond a certain distance from the band the air pressure due to the fundamental frequencies is below the audible limit for the human ear.

Applying this effect to indoor listening, it is clear that if the overture to the "Mastersingers" is reproduced at a level readily drowned by conversation, the musical balance is lost and the orchestra would be just as effective if it consisted of a flute and a few violins. Going to the opposite extreme, most of us have experienced the 'giant' voice of the announcer when the receiver is set to reproduce at a loud level for orchestral work. The voice is then projected at many times its normal loudness and air pressure distortion occurs. By virtue of the aural characteristics, the low tones appear unduly loud, thereby masking the naturalness of the voice. Sometimes this is due to diaphragm or other resonances, but undistorted reproduction at a much greater level than the original always accentuates the lower register. In this respect a violin reproduced very loudly might pass for a 'cello, and a flute for the diapason of a pedal organ.

As a general rule, there are one or more positions of a loud speaker which will give the best results in the average room. Here, as in the design of such instruments, one is often faced with 'Hobson's choice'. Thus reproduction is marred by resonances due to cabinets in which not only the loud speaker but also the whole receiving equipment is housed. The acoustic output is lavished mainly on the carpet, thereby causing attenuation of the upper frequencies and an inferior distribution of sound. When the time comes for a really high standard of reproduction in the home, the acoustic properties of rooms—amongst other things—will have to be taken into serious consideration.

---

[*] This estimate is independent of the power valve and transformer.

[†] It is assumed that the horn structure is substantially dead.

[‡] Damping is greater, due to the restive load imposed by the horn. The magnetic field also assists.

News and Views.

A PUBLIC and official celebration of the British Association centenary took place at Liverpool Cathedral on Sunday, Sept. 20, with the main object of paying tribute to the special associations which Liverpool can claim with the original formation of the Association. A special liturgy of thanksgiving for the works of great natural philosophers of all races and nations throughout the ages was read by Prof. J. L. Myres, one of the general secretaries of the Association, and responded to by the Dean and choir and the congregation. Special emphasis was placed on the public avowal of the debt of churchmen to science and an open recognition of common tasks and common aspirations. This great change in the relations between science and religion since the days of Darwin and Huxley was manifest in the Cathedral addresses of General Smuts and Sir Oliver Lodge and in the special sermon preached by the Bishop of Birmingham. Dr. Barnes remarked that the centenary coincides with the most magnificent period of scientific discovery in the history of humanity. Against this we have literature and art of which, according to Dr. Barnes, little will survive, ethical weakness testified by war, and religious decay. A hundred years ago, geological conceptions began to assail contemporary religious theory. As an antidote arose the Oxford movement. Such opposition still persists, but there are friends of science within the Church. Scientific workers are, like Darwin in the face of the antagonism of Wilberforce, then Bishop of Oxford, going steadily on, and are helping clergy to gain a richer certainty of God's existence and glory. The task before us, since the great advance in biological, physical, and all other sciences, is to make a satisfactory synthesis of man's religious aspirations and the conclusions of modern science.

SUFFICIENT interest has been aroused in the celebration of the centenary of the British Association for the general reader, as well as the student of the history of science, to desire a detailed and connected account of the events which have led up to the present commemoration. The need is admirably met by the issue of a second edition of Mr. Howarth's "The British Association for the Advancement of Science", originally published in 1922. Among the new features is a chapter on Down House—the home of Darwin—presented to the Association by Mr. Buckston Browne. The book contains excellent portraits of many of the Association's most distinguished members, taken at those periods of their lives when scientific discovery and achievement had produced a serenity of bearing, a pleasure to behold. In the first instance, the book was made possible through the generosity of the late Sir Charles Parsons, and its creditable compilation is the outcome of the labours of the secretary of the Association. The Association traverses all the domains of the realms of science, and treks to all the dominions of our Empire. Previously to this year it has regarded a visit to London in the nature of carrying coals to Newcastle; but now it has come and set the City ablaze. The British Association is a monument to the genius of our nation, and Mr. Howarth's book provides a brilliant floodlight to illuminate and advertise the fact. Copies are being presented to members of Association attending the London meeting.

MEMBERS of the British Association are also receiving a copy of "London and the Advancement of Science", a volume of some three hundred pages, compiled by ten contributors, each authoritative in his particular theme. As a preliminary classification of its contents, one might say that the scientific soul of London is revealed in such chapters as those on the learned societies, Government and scientific research, the development of medicine, and the history of education in London; while the more material aspect of the metropolis is dealt with in the sections on the Royal Observatory at Greenwich, Kew Gardens, the John Innes Institution, and the museums of London. There is also an introductory survey and a brief history of the London makers of scientific instruments. Among the authors' names are those of Sir Frank Heath, Sir Frank Dyson, Sir Daniel Hall, and Dr. F. A. Bather. Nothing so worthy of this phase of London life has ever before been attempted or achieved. There is a surfeit of good things for instructor and the instructed. In our youth we were told that the streets of London were paved with gold; we have only to turn to a random page of this book to discover treasures that historians of science, in their maturer years, might accept as precious metal. When Sir Humphry and Lady Davy, after a long stay abroad, arrived home, they mutually agreed that, although the Continent is a nice place to visit, London is the best place to live in. The more one becomes acquainted with the scientific history of London, the more one feels in spiritual contact with its glorious past, and in living union with its quickening present.

THE Faraday Commemorative Meeting, organised by the Royal Institution and the Institution of Electrical Engineers, was held at the Queen's Hall on Sept. 21. Representatives of forty-two countries attended this brilliant and dignified opening of the centenary celebrations in honour of the father of modern physics. In spite of the present crisis, the Prime Minister, the Right Hon. J. Ramsay MacDonald, honoured the meeting by his presence, and paid a warm tribute, in his opening address, to Faraday, the man who lived for his scientific convictions. The prominent speakers who followed laid stress on some particular points of Faraday's discoveries connected with their own special researches.

THE Duc de Broglie, well known for his investigations on X-ray spectra, contrasted the variety of Faraday's experiments with the unity of his purpose —a deeper knowledge of the laws of Nature. The Marchese Marconi explained how wireless and its

Supplement to NATURE

No. 3230 SEPTEMBER 26, 1931

The Scientific World-Picture of To-day.

By General the Right Hon. J. C. SMUTS, P.C., C.H., F.R.S., President of the British Association.

PRESIDENTIAL ADDRESS DELIVERED IN LONDON ON SEPT. 23, 1931.

THIS centenary meeting of the British Association is a milestone which enables us to look back upon a hundred years of scientific progress such as has no parallel in history. It brings us to a point in the advance from which we can confidently look forward to fundamental solutions and discoveries in the near future which may transform the entire field of science. In this second and greater renaissance of the human spirit, this Association and its members have borne a foremost part, to which it would be impossible for me to do justice. I shall therefore not attempt to review the achievements of this century of science, but shall content myself with the simpler undertaking of giving a generalised composite impression of the present situation in science.

I am going to ask the question : What sort of world-picture is science leading to ? Is science tending towards a definite scientific outlook on the universe, and how does it differ from the traditional outlook of commonsense ?

The question is not without its interest. For our world-view is closely connected with our sense of ultimate values, our reading of the riddle of the universe, and of the meaning of life and of human destiny. Our scientific world-picture will draw its material from all the sciences. Among these, physical science will—in view of its revolutionary discoveries in recent years—be a most important source. But no less important will be the contribution of the biological sciences, with their clear revelation of organic structure and function as well as of organic evolution. Last, not least, the social and mental sciences will not only supply valuable material, but also especially methods of interpretation, insights into meanings and values, without which the perspectives of our world-picture would be hopelessly wrong.

Can we from some reunion or symposium of these sciences obtain a world-picture or synoptic view of the universe, based on observation and calculation, which are the instruments of science, but reaching beyond the particular phenomena which are its immediate field to a conception of the universe as a whole ?

That was how science began—in the attempt to find some simple substances or elements to which the complex world of phenomena could in the last analysis be reduced. The century over which we now look back, with its wonderful advance in the methods and technique of exact observation, has been a period of specialisation or decentralisation. Have we now reached a point where science can again become universal in its ultimate outlook ? Has a scientific world-picture become possible ?

Of course there can be no final picture at any one stage of culture. The canvas is as large as the universe, and the moving finger of humanity itself will fill it in from age to age. All the advances of knowledge, all the new insights gained from those advances, will from time to time be blended into that picture. To the deeper insight of every era of our human advance there has been some such world-picture, however vague and faulty. It has been continually changing with the changing knowledge and beliefs of man. Thus, there was the world of magic and animism, which was followed by that of the early Nature gods. There was the geocentric world, which still survives in the world of commonsense. There is the machine or mechanistic world-view dominant since the time of Galileo and Newton, and now, since the coming of Einstein, being replaced by the mathematician's conception of the universe as a symbolic structure of which no mechanical model is possible. All these world-views have in turn obtained currency according as some well-defined aspect of our advancing knowledge has from time to time been dominant. My object is to focus attention on the sort of world-picture which results from the advances of physical, biological, and mental science during the period covered roughly by the activities of our Association.

Science arose from our ordinary experience and commonsense outlook. The world of commonsense is a world of matter, of material stuff, of real separate things and their properties which act on each other and cause changes in each other. To the various things observable by the senses were added the imperceptible things—space and time, invisible forces, life, and the soul. Even these were not enough, and the supernatural was added to the natural world. The original inventory was continually being enlarged, and thus a complex empirical world-view arose, full of latent contradictions, but with a solid basis of actual experience and facts behind it.

Speaking generally, we may say that this is substantially still the commonsense view of the world and the background of our common practical beliefs. How has science dealt with this commonsense empirical world-view? The fundamental procedure of science has been to rely on sense observation and experiment, and to base theory on fact. Thus the vast body of exact science arose, and all entities were discarded which were either inconsistent with observed facts or unnecessary for their strict interpretation. The atomic view of matter was established. Ether was given a status in the physical order which is now again being questioned in the light of the conception of space-time. New entities like energy emerged; old entities like forces disappeared; the principle of the uniformity of Nature was established; the laws of motion, of conservation, and of electromagnetism were formulated; and on their basis a closed mechanistic order of Nature was constructed, forming a rigid deterministic scheme. Into this scheme it has been difficult, if not impossible, to fit entities like life and mind; and the scientific attitude has on the whole been to put them to a suspense account and to await developments. As to the supernatural, science is or has been agnostic, if not frankly sceptical.

Such, in very general terms, was the scientific outlook of the nineteenth century, which has not yet completely passed away. It will be noticed that much of the fundamental outlook of commonsense has thus survived, though clarified and purified by a closer accord with facts. This scientific view retained unimpaired, and indeed stressed with a new emphasis, the things of commonsense, matter, time, and space, as well as all material or physical entities which are capable of observation or experimental verification. Nineteenth-century science is, in fact, a system of purified, glorified commonsense. Its deterministic theory certainly gave a shock to the common man's instinctive belief in free will; in most other respects it conformed to the outlook of commonsense. It is true that its practical inventions have produced the most astounding changes in our material civilisation, but neither in its methods nor in its world-outlook was there anything really revolutionary.

Underneath this placid surface the seeds of the future were germinating. With the coming of the twentieth century fundamental changes began to set in. The new point of departure was reached when physical science ceased to confine its attention to the things that are observed It dug down to a deeper level, and below the things that appear to the senses it found, or invented, at the base of the world, so-called scientific entities, not capable of direct observation, but which are necessary to account for the facts of observation. Thus, below molecules and atoms still more ultimate entities appeared; radiations, electrons, and protons emerged as elements which underlie and form our world of matter. Matter itself, the time-honoured mother of all, practically disappeared into electrical energy.

"The cloud-capp'd towers, the gorgeous palaces,
The solemn temples, the great globe itself,"

yea, all the material forms of earth and sky and sea, were dissolved and spirited away into the blue of energy. Outstanding among the men who brought about this transformation are two of my predecessors in this chair: Sir J. J. Thomson and Lord Rutherford. Like Prospero, like Shakespeare himself, they must be reckoned among the magicians.

Great as was this advance, it does not stand alone. Away in the last century, Clerk Maxwell, following up Faraday's theories and experiments, had formulated his celebrated equations of the electromagnetic field, which applied to light no less than to electromagnetism, and the exploration of this fruitful subject led Minkowski to the amazing discovery in 1908 that time and space were not separate things, but constituent elements in the deeper synthesis of space-time. Thus time is as much of the essence of things as space; it enters from the first into their existence as an integral element. Time is not something extra and superadded to things in their behaviour, but is integral and basic to their constitution. The stuff of the world is thus envisaged as events instead of material things.

This physical concept or insight of space-time is our first revolutionary innovation, our first complete break with the old world of commonsense. Already it has proved an instrument of amazing power in the newer physics. In the hands of an Einstein it has led, beyond Euclid and Newton, to the recasting of the law and the concept of gravitation, and to the new relativity conception of the basic structure of the world. The transformation of the concept of space, owing to the injection into it of time, has destroyed the old passive homogeneous notion of space and has substituted a flexible, variable continuum, the curvatures and unevenness of which constitute to our senses what we call a material world. The new concept has made it possible to construe matter, mass, and energy as but definite measurable conditions of curvature in the structure of space-time. Assuming that electromagnetism will eventually follow the fate of gravitation, we may say that space-time will then appear as the scientific concept for the only physical reality in the universe, and that matter and energy in all their forms will have disappeared as independent entities, and will have become mere configurations of this space-time. This will probably involve an amplified concept of space-time. Einstein has recently indicated that for further advance a modification in our space-time concept will become necessary, and that the additional element of direction will have to be incorporated into it. Whatever change may become necessary in our space-time concept, there can be no doubt about the immense possibilities it has opened up.

I pass on to an even more revolutionary recent advance of physics. The space-time world, however novel, however shattering to commonsense, is not in conflict with reason. Indeed, the space-time world is largely a discovery of the mathematical reason, and is an entirely rational world. It is a world where reason, as it were, dissolves the refractoriness of the old material substance and smoothes it out into forms of space-time. Science, which began with empirical brute facts, seems to be heading for the reign of pure reason. But wait a bit; another fundamental discovery of our age has apparently taken us beyond the bounds of rationality, and is thus even more revolutionary than that of space-time. I refer to the quantum theory, Max Planck's discovery at the end of the nineteenth century, according to which energy is granular, consisting of discrete grains or quanta. The world in space-time is a continuum; the quantum action is a negation of continuity. Thus arises the contradiction, not only of commonsense, but apparently also of reason itself. The quantum appears to behave like a particle, but a particle out of space or time. As Sir Arthur Eddington graphically puts it: a quantum of light is large enough to fill the lens of a hundred-inch telescope, but it is also small enough to enter an atom. It may spread like a circular wave through the universe, but when it hits its mark this cosmic wave instantaneously contracts to a point where it strikes with its full and undivided force.

Space-time, therefore, does not seem to exist for the quantum, at least not in its lower multiples. Nay, more: the very hitting of its mark presents another strange puzzle, which seems to defy the principles of causation and of the uniformity of Nature, and to take us into the realm of chance and probability. The significant thing is that this strange quantum character of the universe is not the result of theory, but is an experimental fact well attested from several departments of physics. In spite of the strange Puck-like behaviour of the quantum, we should not lightly conclude, with some prominent physicists, that the universe has a skeleton in its cupboard in the shape of an irrational or chaotic factor. Our macroscopic concepts may not fit this ultra-microscopic world of the quantum. Our best hopes for the future are founded on the working out of a new system of concepts and laws suited to this new world that has swum into the ken of science. The rapid development of wave mechanics in the last four years seems to have brought us within sight of this ideal, and we are beginning to discern a new kind of order in the microscopic elements of the world, very different from any type of law hitherto imagined in science, but none the less a rational order capable of mathematical formulation.

We may summarise these remarks by saying that the vastly improved technique of research has led to physical discoveries in recent years which have at last completely shattered the traditional commonsense view of the material world. A new space-time world has emerged which is essentially immaterial, and in which the old-time matter, and even the scientific mass, gravitation, and energy stand for no independent entities, but can best be construed as configurations of space-time; and the discovery of the quantic properties of this world points to still more radical transformations which loom on the horizon of science. The complete recasting of many of our categories of experience and thought may ultimately be involved.

From the brilliant discoveries of physical science we pass on to the advances in biological science which, although far less revolutionary, have been scarcely less important for our world-outlook. The most important biological discovery of the last century was the great fact of organic evolution; and for this fact the space-time concept has at last come to provide the necessary physical basis. It is unnecessary for my purpose to canvass the claims and discuss the views represented by the great names of Lamarck, Darwin, and Mendel, beyond saying that they represent a progressive advance in biological discovery, the end of which has by no means been reached yet. Whatever doubts and differences of opinion there may be about the methods, the mechanism, or the causes, there is no doubt about the reality of organic evolution, which is one of the most firmly established results in the whole range of science. Palæontology, embryology, comparative anatomy, taxonomy, and geographical distribution all combine to give the most convincing testimony that, throughout the history of this earth, life has advanced genetically from at most a few simple primitive forms to ever more numerous and highly specialised forms. Under the double influence of the internal genetic and the external environmental factors, life has subtly adapted itself to the ever-changing situations on this planet. In the process of this evolution not only new structures and organs, but also new functions and powers have successively appeared, culminating in the master key of mind and in the crowning achievement of human personality. To have hammered the great truth of organic evolution into the consciousness of mankind is the undying achievement of Charles Darwin, by the side of which his discovery of natural selection as the method of evolution is of secondary importance.

The acceptance of the theory of evolution has brought about a far-reaching change in our outlook on the universe and our sense of values. The story of creation, so intimately associated with the groundwork of most religions, has thus come to be rewritten. The unity and interconnexions of life in all its manifold forms have been clearly recognised, and man himself has had to come down from his privileged position among the angels and take his proper place in the universe as part of the order of Nature. Thus Darwin completes the revolution begun by Copernicus.

Space-time finds its natural completion in organic evolution. For in organic evolution the time aspect of the world finds its most authentic expression. The world truly becomes process, where nothing ever remains the same or is a duplicate of anything else, but a growing, gathering, creative stream of unique events rolls forever forward.

While we recognise this intimate connexion between the conceptions of space-time and organic evolution, we should be careful not to identify the time of evolution with that of space-time. There is a very real difference between them. Biological time has direction, passes from the past to the future, and is therefore historical. It corresponds to the 'before' and 'after' of our conscious experience. Physical time as an aspect of space-time is neutral as regards direction. It is space-like, and may be plus or minus, but does not distinguish between past or future. It may move in either direction, backwards or forwards, while biological time, like the time of experience, knows only a forward flow. Hence cosmic evolution, as we see it in astronomy and physics, is mostly in an opposite direction to that of organic evolution. While biological time on the whole shows a forward movement towards ever higher organisation and rising qualities throughout the geological ages, the process of the physical world is mostly in the opposite direction *—towards disorganisation, disintegration of more complex structures, and dissipation of energy. The second law of thermodynamics thus marks the direction of physical time. While the smaller world of life seems on the whole to be on the up-grade, the larger physical universe is on the down-grade. One may say that in the universe we witness a majority movement downward, and a minority movement upward. The energy which is being dissipated by the decay of physical structure is being partly taken up and organised into life structures—at any rate on this planet. Life and mind thus appear as products of the cosmic decline, and arise like the phœnix from the ashes of a universe radiating itself away. In them Nature seems to have discovered a secret which enables her to irradiate with imperishable glory the decay to which she seems physically doomed.

Another striking point arises here. Organic evolution describes the specific process of what we call life, perhaps the most mysterious phenomenon of this mysterious universe. When we ask what is the nature of life we are curiously reminded of the behaviour of the quantum referred to. I do not for a moment wish to say that the quantum is the physical basis of life, but I do say that in the quantum the physical world offers an analogy to life which is at least suggestive. The quantum follows the all-or-nothing law and behaves as an indivisible whole : so does life. A part of a quantum is not something less than a quantum ; it is nothing or sheer nonentity : the same holds true of life.

---

* No doubt there are exceptions to this broad generalisation. In astronomy stars and solar systems and galaxies are probably still being formed, while in physics syntheses of elements may possibly still be going on. In the same way we find in organic evolution minor phases of regression, degeneration, and parasitism.

The quantum is perhaps most easily symbolised as a wave or combination of waves, which can only exist as a complete periodicity, and the very concept of which negatives its existence as partial or truncated. In other words, it is a specific configuration and can only exist as such: the same holds true of life. The quantum does not fall completely within the deterministic causal scheme: the same seems true of life.

Significant, also, is the fact that quantum phenomena underlie secondary qualities such as colour and the like, which the older science in its mechanistic scheme ignored, but which are specially associated with life and consciousness. Life is not an entity, physical or other. It is a type of organisation; it is a specific principle of central or self organisation. If that organisation is interfered with we are left, not with bits of life, but with death. The nature of living things is determined, not by the nature of their parts, but by the nature or principle of their organisation. In short, the quantum and life seem to have this in common, that they both behave as wholes.

I have before now endeavoured to explore the concept of life in the light of the more general concept of the whole. A whole is not a sum of parts, or constituted by its parts. Its nature lies in its constitution more than in its parts. The part in the whole is no longer the same as the part in isolation. The interesting point is that while this concept of the whole applies to life, it is according to the recent physics no less applicable to the ultimate physical units. Thus the electron within an atom is no longer a distinct electron. There may be separate electrons, but when they cease to be separate they also cease to be. The eight electrons which circulate in an oxygen atom are merged in a whole in such a way that they have lost their separate identity; and this loss of individuality has to be taken into account in calculations as to the physical behaviour of the atom. The physicist, in fact, finds himself unable to look upon the entity which is one-eighth of eight electrons as the same thing as a single electron. At the very foundation, therefore, of physics, the principle or category of the whole applies no less than in the advanced structure of life, although not in the same degree. In the ultimate analysis of the world, both at the physical and the biological level, the part or unit element somehow becomes shadowy and incoherent, and the very basis of mechanism is undermined. It would almost seem as if the world in its very essence is holistic, and as if the notion of individual parts is a practical makeshift without final validity in the nature of things.

The general trend of the recent advances in physics has thus been towards the recognition of the fundamental organic character of the material world. Physics and biology are beginning to look not so utterly unlike each other. Hitherto the great gulf in Nature has lain between the material and the vital, between inorganic matter and life. This gulf is now in process of being bridged. The new physics, in dissolving the material world of common sense and discovering the finer structure of physical Nature, has at the same time disclosed certain fundamental features which it has in common with the organic world. Stuff-like entities have disappeared and have been replaced by space-time configurations, the very nature of which depends on their principle of organisation. This principle, which I have ventured to call holism, appears to be at botton identical with that which pervades the organic structures of the world of life. The quantum and space-time have brought physics closer to biology. As I have pointed out, the quantum anticipates some of the fundamental characters of life, while space-time forms the physical basis for organic evolution. Physics and biology are thus recognised as respectively simpler and more advanced forms of the same fundamental pattern in world-structure.

The older mechanistic conception of Nature, the picture of Nature as consisting of fixed material particles, mechanically interacting with each other—already rudely shaken by the relativity theory—is now being modified by the quantum physics. The attack on mechanism, thus coming from physical science itself, is therefore all the more deadly. Even in physics, organisation is becoming more important than the somewhat nebulous entities which enter into matter. Interaction is more and more recognised to be not so much mechanical as organic or holistic, the whole in some respects dominating not only the functioning but also the very existence of the entities forming it. The emergence of this organic view of Nature from the domain of physics itself is thus a matter of first-rate importance, and must have very far-reaching repercussions for our eventual world-view.

The nature of the organic whole is, however, much more clearly recognised in its proper sphere of biology, and especially in the rapidly advancing science of physiology. Here, too, the correct view has been much obscured by the invasion of mechanistic ideas from the physics of the nineteenth century. A crude materialism all but swamped biology for more than a generation. At the Belfast meeting of the British Association in 1874, a famous predecessor of mine gave unrestrained expression to this materialistic creed. All that is passing, if not already past. It must be admitted that up to a point mechanism has been useful as a first approximation and fruitful as a convention for research purposes. But if even in physics it has lost its savour, *a fortiori* has it become out of place in biology. The partial truth of mechanism is always subtended by the deeper truth of organicity or holism. So far from biology being forced into a physical mould, the position will in future be reversed. Physics will look to biology and even to psychology for hints, clues, and suggestions. In biology and psychology it will see principles at work in their full maturity which can only be faintly and fitfully recognised in physics. In this way the exchanges of physics, biology, and psychology will become fruitful for the science of the future, and lay the basis for a new scientific monism.

A living individual is a physiological whole, in which the parts or organs are but differentiations of this whole for purposes of greater efficiency, and remain in organic continuity throughout. They are parts *of* the individual, and not independent or self-contained units which *compose* the individual. It is only this conception of the individual as a dynamic organic whole which will make intelligible the extraordinary unity which characterises the multiplicity of functions in an organism, the mobile, ever-changing balance and interdependence of the numerous regulatory processes in it, as well as the operation of all the mechanisms by which organic evolution is brought about. This conception applies not only to individuals, but also to organic societies, such as a beehive or an ants' nest, and even to social organisations on the human level.

As the concept of space-time destroys the purely spatial character of things, so the concept of the organic whole must also be extended beyond the spatial limits of the organism so as to include its interaction with its environment. The stimuli and responses which render them mutually interdependent constitute them one whole which thus transcends purely spatial aspects. It is this overflow of organic wholes beyond their apparent spatial limits which binds all Nature together and prevents it from being a mere assemblage of separate interacting units.

It is time, however, that we pass on to the world of mind. From matter, as now transformed by space-time and the quantum, we pass step by step through organic nature to conscious mind. Gone is the time when Descartes could divide the world into only two substances: extended substance or matter, and thinking substance or mind. There is a whole world of gradations between these two limits. On Descartes' false dichotomy the separate provinces of modern science and philosophy were demarcated. But it is as dead as the epicycles of Ptolemy, and ultimately the Cartesian frontiers between physics and philosophy must largely disappear, and philosophy once more become metaphysic in the original sense. In the meantime, under its harmful influence, the paths of matter and mind, of science and philosophy, were made to diverge farther and farther, so that only the revolution now taking place in thought could bring them together again. I believe, however, their reunion is coming fast. We have seen matter and life indefinitely approaching each other in the ultimate constituents of the world. We have seen that matter is fundamentally a configuration or organisation of space-time; and we have seen that life is a principle of organisation whereby the space-time patterns are arranged into organic unities. The next step is to show that mind is an even more potent embodiment of the organising whole-making principle, and that this embodiment has found expression in a rising series, which begins practically on the lowest levels of life, and rises ultimately to the conscious mind which alone Descartes had in view in his classification. I have no time to follow up the matter here beyond making a few remarks.

Mind is admittedly an active, conative, organising principle. It is for ever busy constructing new patterns of things, thoughts, or principles out of the material of its experience. Mind, even more than life, is a principle of whole-making. It differentiates, discriminates, and selects from its vague experience, and fashions and correlates the resulting features into more or less stable, enduring wholes. Beginning as mere blind tropisms, reflexes, and conditioned reflexes, mind in organic Nature has advanced step by step in its creative march until in man it has become Nature's supreme organ of understanding, endeavour, and control—not merely a subjective human organ, but Nature's own power of self-illumination and self-mastery: "The eye with which the universe beholds itself and knows itself divine".

The free creativeness of mind is possible because, as we have seen, the world ultimately consists, not of material stuff, but of patterns, of organisation, the evolution of which involves no absolute creation of an alien world of material from nothing. The purely structural character of reality thus helps to render possible and intelligible the free creativeness of life and mind, and accounts for the unlimited wealth of fresh patterns which mind freely creates on the basis of the existing physical patterns.

The highest reach of this creative process is seen in the realm of values, which is the product of the human mind. Great as is the physical universe which confronts us as a given fact, no less great is our reading and evaluation of it in the world of values, as seen in language, literature, culture, civilisation, society and the State, law, architecture, art, science, morals, and religion. Without this revelation of inner meaning and significance the external physical universe would be but an immense empty shell or crumpled surface. The brute fact here receives its meaning, and a new world arises which gives to Nature whatever significance it has. As against the physical configurations of Nature we see here the ideal patterns or wholes freely created by the human spirit as a home and an environment for itself.

Among the human values thus created science ranks with art and religion. In its selfless pursuit of truth, in its vision of order and beauty, it partakes of the quality of both. More and more it is beginning to make a profound æsthetic and religious appeal to thinking people. Indeed, it may fairly be said that science is perhaps the clearest revelation of God to our age. Science is at last coming into its own as one of the supreme goods of the human race.

While religion, art, and science are still separate values, they may not always remain such. Indeed, one of the greatest tasks before the human race will be to link up science with ethical values, and thus to remove grave dangers threatening our future. A serious lag has already developed between our rapid scientific advance and our stationary ethical development, a lag which has already found expression in the greatest tragedy of history. Science must itself help to close this dangerous gap in our advance which threatens the disruption of our civilisation and the decay of our species. Its final and perhaps most difficult task may be found just here. Science may be destined to become the most effective drive towards ethical values, and in that way to render its most priceless human service. In saying this I am going beyond the scope of science as at present understood, but the conception of science itself is bound to be affected by its eventual integration with the other great values.

I have now finished my rapid and necessarily superficial survey of the more prominent recent tendencies in science, and I proceed to summarise the results and draw my conclusions, in so far as they bear on our world-picture.

In the first place we have seen that in the ultimate physical analysis, science reaches a microscopic world of scientific entities, very different in character and behaviour from the macroscopic world of matter, space, and time. The world of atoms, electrons, protons, radiations, and quanta does not seem to be in space-time or to conform to natural law in the ordinary sense. The behaviour of these entities cannot be understood without the most abstruse mathematics or, apparently, without resort to epistemological considerations. We seem to have passed beyond the definitely physical world into a twilight where prophysics and metaphysics meet, where space-time does not exist, and where strictly causal law in the old sense does not apply. From this uncertain nebulous underworld there seems to crystallise out, or literally to materialise, the macroscopic world which is the proper sphere of sensuous observation and of natural laws. The pre-material entities or units condense and cohere into constellations, which increase in size and structure until they reach the macroscopic stage of observation. As the macroscopic entities emerge, their space-time field and appropriate natural laws (mostly of a statistical character) emerge *pari passu*. We seem to pass from one level to another in the evolution of the universe, with different units, different behaviours, and calling for different concepts and laws. Similarly, we rise to new levels as later on we pass from the physical to the biological level, and again from the latter to the level of conscious mind But—and this is the significant fact—all these levels are genetically related and form an evolutionary series ; and underlying the differences of the successive levels, there remains a fundamental unity of plan or organisation which binds them together as members of a genetic series, as a growing, evolving, creative universe.

In the second place, let us see how common sense deals with this macroscopic world. On this stage common sense recognises three levels of matter, life, and mind as together composing the world. But it places them so far apart, and makes them so inherently different from each other, that relations between them appear unintelligible, if not impossible. The common-sense notions of matter, life, and mind make any relations between them, as well as the world which they form, an insoluble puzzle. The older science therefore attempted to reduce life substantially to terms of matter, and to put a question mark behind mind ; and the result was a predominantly materialistic view of the world. The space-time relativity concept of the world has overcome the difficulty by destroying the old concept of matter, and reducing it from a self-subsistent entity to a configuration of space-time—in other words, to a special organisation of the basic world-structure. If matter is essentially immaterial structure or organisation, it cannot fundamentally be so different from organism or life, which is best envisaged as a principle of organisation ; or from mind, which is an active organiser.

Matter, life, and mind thus translate roughly into organisation, organism, organiser. The all-or-none law of the quantum, which also applies to life and mind, is another indication that matter, life, and mind may be but different stages or levels of the same activity in the world which I have associated with the pervading feature of whole-making. Materialism has thus gone by the board, and the unintelligible trinity of common sense (matter, life, mind) has been reinterpreted and transformed and put on the way to a new monism.

In the third place, the iron determination of the older science, so contrary to direct human experience, so destructive of the free activity of life and mind, as well as subversive of the moral responsibility of the individual, has also been materially recast. It was due to the Newtonian causal scheme which, as I have indicated, has been profoundly shaken by recent developments. Relativity reduces substance to configuration or patterns, while quantum physics gives definite indications of indeterminism in Nature. In any case, life through the ages shows clearly a creative advance to ever more complex organisation, and ever higher qualities, while mind is responsible for the creation of a whole realm of values. We are thus justified in stressing, along with natural necessity, an increasing measure of freedom and creativeness in the world, sufficient at least to account for organic evolution and for the appearance of moral law and endeavour

This liberation of life and spirit from the iron rule of necessity is one of the greatest gains from the recent scientific advances. Nature is not a closed physical circle, but has left the door open to the emergence of life and mind and the development of human personality. It has, in its open flexible physical patterns, laid the foundation and established the environment for the coming of life and mind. The view, to which Huxley once gave such eloquent and poignant expression, of a dualism implanted in the heart of Nature, of a deadly struggle between cosmic law and moral law, is no longer justified by the subsequent advances of science.

In the fourth place, however, another dualism of a wider reach has appeared, which makes the universe itself appear to be a house divided against itself. For while the stream of physical tendency throughout the universe is on the whole downward, toward disintegration and dissipation, the organic movement, on this planet at least, is upward, and life structures are on the whole becoming more complex throughout the course of organic evolution. From the viewpoint of physics, life and mind are thus singular and exceptional phenomena, not in line with the movement of the universe as a whole. Recent astronomical theory has come to strengthen this view of life as an exceptional feature off the main track of the universe. For the origin of our planetary system is attributed to an unusual accident, and planets such as ours with a favourable environment for life are taken to be rare in the universe. Perhaps we may even say that at the present epoch there is no other globe where life is at the level manifested on the earth. Our origin is thus accidental, our position is exceptional, and our fate is sealed, with the inevitable running down of the solar system. Life and mind, instead of being the natural flowering of the universe, are thus reduced to a very casual and inferior status in the cosmic order. A new meaning and a far deeper poignancy are given to Shakespeare's immortal lines :

> " We are such stuff
> As dreams are made of ; and our little life
> Is rounded with a sleep."

According to astronomy, life is indeed a lonely and pathetic thing in this physical universe—a transient and embarrassed phantom in an alien, if not hostile, universe.

Such are some of the depressing speculations of recent astronomical theory. But in some respects they have already been discounted in the foregoing. For even if life be merely a terrestrial phenomenon, it is by no means in an alien environment if, as we have seen reason to think, this is an essentially organic universe. In its organic aspects the universe is on the way to life and mind, even if the goal has been actually reached at only one insignificant point in the universe. The potencies of the universe are fundamentally of the same order as its actualities. The universe might say, in the words of Rabbi Ben Ezra :

> " All I could never be
> All man ignored in me,
> This I was worth to God."

Then again, the very possibility of perception, of knowledge and science, depends on an intimate relation between mind and the physical universe. Only thus can the concepts of mind come to be a measure for the facts of the universe, and the laws of Nature come to be revealed and interpreted by Nature's own organ of the human mind. Besides science we have other forms of this inner relation between the mind and the universe, such as poetry, music, art, and religion. The human spirit is not a pathetic wandering phantom of the universe, but is at home, and meets with spiritual hospitality and response everywhere. Our deepest thoughts and emotions and endeavours are but responses to stimuli which come to us, not from an alien, but from an essentially friendly and kindred universe. So far from the cosmic status of life and mind being degraded by the newer astronomy and physics, I would suggest an alternative interpretation of the facts, more in accord with the trend of evolutionary science. We have seen a macroscopic universe born or revealed to consciousness out of a prior microscopic order of a very different character. Are we not, in the emergence of life and mind, witnessing the birth or revelation of a new world out of the macroscopic physical universe ? I suggest that at the present cosmic epoch we are the spectators of what is perhaps the grandest event in the immeasurable history of our universe, and that we must interpret the present phase of the universe as a mother and child universe, still joined together by a placenta which science, in its divorce from the other great values, has hitherto failed to unravel.

Piecing together these clues and conclusions, we arrive at a world-picture fuller of mystery than ever. In a way it is closer to common sense and kinder to human nature than was the science of the nineteenth century. Materialism has practically disappeared, and the despotic rule of necessity has been greatly relaxed. In ever-varying degree the universe is organic and holistic through and through. Not only organic concepts, but also, and even more so, psychological viewpoints are becoming necessary to elucidate the facts of science ; and while the purely human concepts, such as emotion and value, purpose and will, do not apply in the natural sciences, they retain their unimpaired force in the human sciences. The ancient spiritual goods and heirlooms of our race need not be ruthlessly scrapped. The great values and ideals retain their unfading glory and derive new interest and force from a cosmic setting.

In other respects it is a strange new universe, impalpable, immaterial, consisting not of material or stuff, but of organisation, of patterns or wholes which are unceasingly being woven to more complex or to simpler designs. In the large it appears to be a decaying, simplifying universe which attained to its perfection of organisation in the far-distant past and is now regressing to simpler forms—perhaps for good, perhaps only to restart another cycle of organisation. But inside this cosmic process of decline we notice a smaller but far more significant movement—a streaming, protoplasmic tendency ; an embryonic infant world emerging, throbbing with passionate life, and striving towards rational and spiritual self-realisation. We see the mysterious creative rise of the higher out of the lower, the more from the less, the picture within its framework, the spiritual kernel inside the phenomenal integuments of the universe. Instead of the animistic, or the mechanistic, or the mathematical universe, we see the genetic, organic, holistic universe, in which the decline of the earlier physical patterns provides the opportunity for the emergence of the more advanced vital and rational patterns.

In this holistic universe man is in very truth the offspring of the stars. The world consists not only of electrons and radiations, but also of souls and aspirations. Beauty and holiness are as much aspects of Nature as energy and entropy. Thus " in eternal lines to time it grows ". An adequate world-view would find them all in their proper context in the framework of the whole ; and evolution is perhaps the only way of approach to the framing of a consistent world-picture which would do justice to the immensity, the profundity, and the unutterable mystery of the universe.

Such in vague outline is the world-picture to which science seems to me to be pointing. We may not all agree with my rendering of it, which indeed does not claim to be more than a mere sketch. Even if it were generally accepted, we have still to bear in mind that the world-picture of to-morrow will in all probability be very different from any which could be sketched to-day.

Summaries of Addresses of Presidents of Sections.*

Education and Research in Physics.

SIR J. J. THOMSON devoted his presidential address to Section A (Mathematical and Physical Sciences) to a discussion of "The Growth in Opportunities for Education and Research in Physics during the Past Fifty Years". The limit of fifty years was inevitable, for organised facilities for teaching and research in physics were almost unknown until towards the end of the nineteenth century. Much of the physical work of Joule, Stokes, Spottiswoode, Huggins, de la Rue, Rayleigh, and E. H. Griffiths was done in private rooms or private laboratories. Instruction was also unorganised. These men, like Kelvin and Maxwell, were in regard to physics largely self-taught, but they had learned to use their hands. In the early 'seventies there were only six physical laboratories in England; now there are considerably more than three hundred.

Sir Joseph traced the history of scientific education in universities and schools. Cambridge determined to establish a natural science tripos in 1849 and the first examination, with six candidates, was held in 1851. This number increased to twenty-five in 1881 and to ninety-four in 1891. The great advance has been made in the last fifty years. "It cannot, however, be said that even now Science occupies in our systems of education a place commensurate with its ever-increasing influence on human thought and with its importance in the progress of civilisation." Canvassing the reasons for this important conclusion, he blamed the scholarship system in universities and public schools, with its undue preference to classics. It was true that the teaching of classics and mathematics had a long experience and tradition behind. But the scholarship system, in some cases, enticed boys along a path not leading to their true destinations.

Passing to post-graduate study and research, Sir Joseph commented on the lack of laboratories, of scholarships, and of opportunities for research workers as retarding influences during the earlier part of the period. He referred to the institution of the Ph.D. degree, and mentioned that there are now forty-five students taking physics at Cambridge in preparation for this degree. The year or two of research work thus provided was chiefly a means of training. If conducted under proper conditions its value could not easily be overrated, but under other conditions it might be positively harmful. This thesis was developed in an important passage on the *differentia* of research work in university laboratories as contrasted with governmental or works laboratories. The aim of the university laboratory should not be to turn out the largest number of small papers, to get results, to discover as many new facts as possible. It was necessary to avoid, even in university workers, over-specialisation and over-concentration. A little teaching might assist the research worker in this respect as providing an interruption. "It is, I think, a general experience that new ideas about a subject come when one is not thinking about it."

Sir Joseph discussed the question of careers for research workers, referring especially to the foundation in 1901 of the National Physical Laboratory, which now employs 160 research workers, and to the establishment in 1915 of the Department of Scientific and Industrial Research. Of the twenty research associations promoted by the Department, he remarked that at first there was plenty of money but no well-trained men, now there are plenty of men but no money; but there were good reasons for thinking that the financial gain to the industries had far exceeded the expenses of the laboratories. Considering research work as a profession, he observed that a worker might spend years without getting results of any very striking importance; he might therefore get depressed, lose hope, and try to transfer to administration or organisation. "The researcher, if he is to have a happy life, must regard the game and not the score as the chief thing."

The increase in the number of research workers had led to a corresponding increase in the number of papers on physics. *Science Abstracts* for 1930 contains abstracts of 4165 papers—very nearly a dozen a day. It was obvious that no one could read more than a fraction of these. He urged the need in physics for something corresponding to the annual report of the Chemical Society and for the publication monthly of the titles of physical papers. Progress in physics had been due in part to the improvement of instruments and appliances; in this way industry had repaid its debt to science. But the development had greatly increased the cost of physical research. Theories were the very lifeblood of physics, but theory may be injurious if it makes the worker treat as an annoyance any anomaly which interferes with progress to the goal.

---

* The collected presidential addresses delivered in London are published under the title "The Advancement of Science, 1931". The volume is obtainable at 5*s*. net of all booksellers, or at the Reception Room by members attending the meeting, 3*s*. 6*d*.

"The anomaly may be the outcrop of a vein rich in new phenomena." He instanced the discovery of argon by Lord Rayleigh as arising from some vexatious discrepancies in a series of weighings. In conclusion, he said that there was no danger of the supply of new physical phenomena being exhausted and of physicists joining the ranks of the unemployed.

FARADAY AND ELECTROLYTIC CONDUCTION.

In his presidential address to Section B (Chemistry), Sir Harold Hartley spoke on "Michael Faraday and the Theory of Electrolytic Conduction". Faraday was in a sense the discovery of a chemist, he was trained in a chemical laboratory, his early triumphs were in the field of chemistry, and he was one of the great masters of chemical technique. He presided over the chemical section of the British Association in 1837 and in 1846. Sir Harold Hartley gives a brief sketch of Faraday's early life and work, emphasising that the intensely personal character of Faraday's work depends on the fact that it was all done with his own hands, and that if he used the results of others he repeated their experiments.

The year 1831 was the turning point of Faraday's career, probably because of the success of an experiment on the production of a current by magnetic induction which he had tried before without results. The experiments on conduction came a year later, leading up to the publication in 1834 of the fundamental laws of electrolysis. In August 1833 Faraday had entered in his note-book a resolve to try "whether the same quantity of electricity always produces an equivalent of chemical decomposition"; a month later he was using the water voltameter for measuring currents; in December he had extended the law to fused salts, and had also made what Sir Harold calls "a remarkable anticipation of modern methods of electrolytic analysis" by suggesting that electrolysis may finally give rise to "a good principle of analysis". A suggestion that the atoms of bodies were associated with equal quantities of electricity was raised by Faraday, but was not developed, since he was not attracted by the atomic theory. Faraday was quite clear on the essential difference between quantity of electricity and electromotive force, a misunderstanding of which led Berzelius to an unjust criticism of Faraday's work.

During the century which has elapsed since Faraday's work there have been three main phases in the development of the problem of the conduction of electricity in solutions. The first was the discovery of the general relationships between conductivity and the concentration and nature of the dissolved substance, due mainly to the work of Hittorf and Kohlrausch. Hittorf in 1853 had realised that the two ions of a salt usually move with different speeds, and showed how the ratio of these speeds could be determined experimentally. Kohlrausch, in 1876, recognised that the ions of a salt move independently, and in 1878 he introduced the conceptions of equivalent conductivity and mobilities which are still in use, at the same time developing the experimental methods.

The second phase was the enunciation of the theory of electrolytic dissociation by Arrhenius in 1887. This was followed by many important applications in different fields of electrochemistry, such as the theory of the galvanic cell due to Nernst. From the beginning, however, Planck and van 't Hoff had shown that the law of mass action does not apply to strong electrolytes if the degree of dissociation is calculated by the Arrhenius method from the ratio of the equivalent conductivity to that at infinite dilution.

The third phase is the quantitative explanation of the properties of electrolytes, and the removal of the difficulty just mentioned, by the mathematical theories due to Milner and to Debye and Hückel. The new theory takes account of the great forces acting between the charged ions, the magnitude of which was clearly perceived by Faraday, and shows how, starting with the idea that electrolytes are completely dissociated in dilute solution, the empirical square-root law of Kohlrausch can be explained quantitatively. Each ion is surrounded by an atmosphere of ions of opposite sign, and the behaviour of this, and of the solvent carried by the ions, leads to the equations. The idea of the ion atmosphere, with a finite time of formation and dispersion, has been proved experimentally by Wien and others, and the extension of Debye's theory by Onsager has been found to represent the behaviour of a perfect electrolyte in dilute solution. In the case of non-aqueous solutions the chemical nature of the solvent and the affinities of the ions seem to be of great importance, and further developments may be expected in these directions.

GEOLOGICAL PROBLEMS CONTEMPORARY WITH THE BRITISH ASSOCIATION.

In his presidential address to Section C (Geology) Prof. J. W. Gregory points out that the first thoughts of geologists at the centenary meeting of the Association are, naturally, homage to the group of geologists who gave it effective support at its foundation, and consideration of the problems on which they were engaged. In 1831 Great Britain held the hegemony of the world in stratigraphy, the nomenclature of which is permeated with English place-names; and Macculloch declared in 1831 that "the study of Arran alone has taught us more than Asia and America united". The British lead was maintained in the decade after 1831 by Lyell's classification of the formations above the Chalk, and by Murchison's foundation of the Silurian System—the first great step in the arrangement of the rocks earlier than the Carboniferous.

The greatest advance in the decade was the publication of Lyell's "Principles of Geology", although they were condemned by some of his contemporaries. Geology at that time was harassed by three uncertainties. The first was the nature of sea-level. Von Buch's view that Scandinavia was being tilted upon a pivot was at first rejected by Lyell as a baseless and extraordinary notion: but he himself proved its truth to the Association in 1834, and thus established the local mobility of the earth's crust. Faith in that mobility has been confirmed by proof that the transference of a thin layer of sediment causes the rise or fall of the surface; some isostacists now hold that the whole of the earth's surface is in delicate equilibrium, and that the oceanic depressions and continental masses are necessarily permanent in position. That conclusion is opposed to weighty geological evidence, and it appears that the parts of the crust that sink with a slight increase of load are limited to unstable bands or asthenostrophes.

Geological progress was hampered in 1831 by firm belief in the fixity of species. Lamarck's view of the transmutation or evolution of one species into another was rejected by Buckland and by Sedgwick, who denounced "all its train of monstrous consequences". But the doctrine was added to the accepted principles of geology by a recruit of 1831. In that year Darwin began the study of geology and sailed as naturalist with the *Beagle*. The fixity of species was supported by theological influences which were then powerful. Buckland, though blamed by fellow-clerics as heterodox, held that each of the six days of Creation was a natural day. Murchison was the doughty pioneer of the freedom of scientific thought in his assertion in 1832 of the "entire disconnexion of our science with the inspired writings".

The nature of mineral veins was discussed by the Association at an early meeting. Ore deposits were then generally attributed to igneous or electric agencies; but their formation by solutions arising along fractures from the interior of the earth was supported by Fournet and by Daubeny in his address to the Association in 1836. This explanation was for a time discarded in favour of the lateral secretion theory; but opinion has returned to the origin of most ores from a layer below the igneous rocks, and their introduction to the upper layers of the crust by the processes that also determine the ascent of the igneous rocks and the uplift of mountains.

The interpretation of mountain chains was advanced by Elie de Beaumont, whose classification of mountain systems was carefully considered by the Association at its early meetings. In 1842 H. D. Rogers expounded the asymmetric nature of mountain folding, a view developed later by Suess, whose demonstration of the frequent world-wide advance of the sea upon the land reconciled opinion to what the geologists of 1831 called "the dogma of universal formations". Evidence from countries then geologically unknown has shown the world-wide range of the geological systems and of most of the great breaks between them; and the century's work indicates that the main course of geological evolution is controlled by the slow deformation of the earth as the crust adapts itself to the contraction of the internal mass.

A CENTENARY OF EVOLUTION.

Prof. E. B. Poulton points out at the beginning of his presidential address to Section D (Zoology) that the fiftieth anniversary of the British Association, celebrated at York, marked a turning-point in evolutionary controversy. From 1860 up to 1881, evolution itself was the subject discussed, often with intense feeling; in the second half-century, evolution has been generally accepted, and discussion has been concentrated upon its motive cause or causes, the size of the steps, and the rate of progress. Darwin's belief in evolution was the result of his observations on the *Beagle*—the five years' voyage, begun on Dec. 27, 1831, which he considered as by far the most important event in his life. The motive cause, natural selection, did not occur to him until 1838, two years after his return. Wallace's independent discovery, twenty years later, also followed his conviction that evolution was a fact.

It was very different with the two earlier originators of the theory, W. C. Wells (1818) and Patrick Matthew (1831), neither of whom realised the significance of his discovery. Robert Chambers'

"Vestiges" contains illuminating thoughts, and has scarcely received its due. Chambers, not known during his life to be the author, was the cause of the great debate at Oxford in 1860, for it was his persuasion which induced Huxley to be present. Canon Tristram, in his paper on the larks of the Sahara, accepted natural selection as the cause of animal colouring in the desert, following the Darwin-Wallace essay (1858) and before the appearance of the " Origin of Species ".

One of the most important subjects discussed in the second half-century was the hereditary transmission of acquired characters, Francis Galton, Ray Lankester, Fairfield Osborn, and Weismann himself taking part in the debates. The re-discovery of Mendel's work on heredity, by emphasising germinal qualities, played an important part in the spread of Weismann's teaching, and also supplied an answer to a difficulty which had troubled Darwin —" the swamping effect of intercrossing ", as stated by Fleeming Jenkin. Mendelism does not conflict with Darwinian evolution as some have supposed. It is, as Miss E. R. Saunders stated at Cardiff, a theory of heredity, not a theory of evolution. One cause of the imaginary conflict was the mistaken belief that mutations were always large variations and evolution therefore discontinuous, also that small variations were not transmitted. American research has abundantly proved, as H. S. Jennings has stated, that extremely small variations are subject to Mendelian heredity and capable of providing material for natural selection, as maintained by R. A. Fisher in his recent work.

Darwinism is also consistent, discontinuity inconsistent, with the palæontological record and with the evolution, of which we see the stages nearly everywhere in the world, of geographical races into true species.

The age of the earth as determined by Lord Kelvin and Prof. Tait, at one time believed to be a great difficulty, made much of by Lord Salisbury at Oxford in 1894, was shown by Prof. Perry, and later by researches on radioactivity, to be mistaken.

The difficulty of accounting for the earliest stages of useful structures is met by Anton Dohrn's principle, 'change of function', a new use being taken over, by an existing organ, and, co-operating with this, by the 'organic selection' of Baldwin, Morgan, and Osborn—the power of individual adaptability (itself, it was maintained, a product of selection), enabling the species to exist until the needful variations have appeared.

Recent alternatives to Darwinian evolution are chiefly if not entirely manifestations of a supposed 'internal developmental force', a belief accounted for by H. W. Bates, in his classical paper on mimicry, by the prolonged " operation of selecting agents " producing " the impression of there being some innate principle in species which causes an advance of organisation in a special direction ". The evolution of a mimetic resemblance being, as Bates maintained, " a problem which involves that of the origin of all species and all adaptations ", is peculiarly suitable as evidence of natural selection—all the more so because the steps of evolution can often be traced.

The concluding section of the address is devoted to the description of examples of insect mimicry and protective resemblance, which, it is claimed, are wholly consistent with Darwinism but with no other theory of evolution.

GEOGRAPHICAL CONCEPTS OF THE HYDROSPHERE AND MOMENTUM.

In his presidential address to Section E (Geography), entitled " The Human Habitat ", Sir Halford Mackinder lays stress on the distinction between the two answers to the question 'Why there ?' If a man stand on a mountain top he is there in the first place because he climbed there ; that is the genetic answer ; and in the second place because he is upheld by the rocks ; that is the dynamic answer. Sir Halford considers that in the development of geography during the last half century there has been excessive stress laid on the genetic side ; in other words, on geomorphology and historical geography. As a result there is no unity of aim as between the two great branches of geography. It is suggested that if the hydrosphere rather than the lithosphere be treated as the main theme and business of the geographer, then a unity and a philosophy common to the whole subject emerge, and also a complete change in practical outlook, because dynamic considerations come to the fore.

Sir Halford starts from the astronomical fact that the liquid state of matter, in which alone life can exist, is limited to a minute part of the universe. A planet with a hydrosphere is therefore a unique object of study. This earth is important, not merely subjectively and because we men who inhabit it are the students ; in the university of the impartial angels it would be an object of intense interest and speculation. May we not compare it with radium among the elements ? Just as radium, almost infinitesimal in quantity, has by its activity revealed the energy locked up in the commoner atoms, so may not the hydrosphere of our earth present the infinitesimally rare conditions under which life becomes active which elsewhere through the universe is immanent, but potential and not active ?

In biogeography the essential unit is the natural region. This is no mere convenient generalisation. Both by origin and effect it is, when considered from the point of view of the hydrosphere, a fundamental fact. Whether high-lying or low-lying it has a certain area or spread, and the ultimate reason of this is that the surface of liquid water is level. The boundaries which separate it from other natural regions are, according to the new trend of hypothesis based on the study of isostasy, also of aqueous origin in that water is the agent redistributing the cargo carried on the floating granitic rafts which are the continents, and the stresses so caused lead both to mountain building and readjustments of coast level. The natural region is fundamental also from the point of view of life, because local varieties are thereby isolated and fixed as new species.

In regard to momentum, Sir Halford draws a distinction. Geographical momentum is a fact of the present and therefore an element in the dynamic analysis and not merely a subject for genetic consideration. Whether he study the present or the past, the geographer is primarily concerned with space and with time only in the sense that everything has momentum. The present consists of a coming out of the past and a going into the future ; there is a complex dynamic present in the sense of a balance of forces, all severally waxing and waning in different degrees. The student of the hydrosphere is concerned with water, sap, and blood, moving under sun power and life initiative. Water carries and stores energy, whether that energy emanate directly from the sun or be controlled by life. Two agents, the sun and life, work in the same medium, water, and must therefore obey the same conditions. These ideas of the hydrosphere and momentum are then applied in this address to a series of illustrations drawn from human geography.

Finally, the conclusion is reached that if our civilisation is not to go down in blind internecine conflict, there must be a development of world planning out of regional planning, just as regional planning has come out of town planning. The peaceful readjustment of treaties to differential growth will postulate an informed and delicate geographical judgment, for geography must underlie the strategy of peace if we would not have it subserve the strategy of war, and in the formation of such a judgment geomorphology cannot play the major part.

THE CHANGED OUTLOOK IN REGARD TO POPULATION, 1831–1931.

In his presidential address to Section F (Economics and Statistics) Prof. E. Cannan shows how changed is the outlook with regard to population in 1931 from that which prevailed in 1831. Modern science has dispelled the belief that no great progress is likely to take place in the arts of agriculture and other kinds of primary production, and birth-control has destroyed the fear that population is likely to increase sufficiently fast to counterbalance the effects of the progress, however great it may be.

At the meeting of the British Association at Ipswich in 1895, Prof. Cannan directed attention to the fact that the annual number of births in Great Britain, after a long period of rapid increase, was becoming stationary, and suggested that the increase of population might diminish and be nearly at an end by the middle of the present century. Subsequent events suggest that the verification of this forecast is nearly at hand, mortality and emigration having indeed diminished, but the number of births being now only about 650,000 per annum in England and Wales instead of the 880,000 which prevailed fifty years ago, and other countries either already showing the same tendency or being likely to do so shortly under the influence of modern knowledge and ideas.

The change requires the abandonment by economists and statesmen of the old emphasis on food production. This is requiring a smaller and smaller proportion of mankind's activity, and it should be recognised that it is more of the healthy luxuries rather than more of the necessaries of life that we want. Schemes for putting more people on the land, either near the centres or on the outskirts of civilisation, are misconceived. So also are all plans based on the belief that ownership of land is likely to take an ever-growing proportion of the whole produce of industry.

It is also wrong to suppose that cessation of the growth of numbers will cure, or at least alleviate, unemployment. The most powerful cause of unemployment is a rapid absolute decline in the demand for particular kinds of labour, and such a decline is more likely to occur in a stationary than in an increasing population. Mobility in regard to both place and occupation is the cure, and is more necessary when the growth of population slackens and ceases.

To the address as printed is appended a table of the births in England and Wales, showing rapid increase from 616,000 in 1851 to 888,000 in 1876, then little change for fifteen years, rather larger figures owing to the decline of the emigration of persons of the reproductive ages from 1884 to 1910, with a maximum of 948,000 in 1903, followed by a decline below the 1876 level before the War. The War sent the number down to 663,000 in 1918, and the return of men after it produced 958,000 in 1920, but this was a short-lived recovery, followed by a steady decline to 654,000, 660,000, 644,000, and 649,000 in the years 1927 to 1930.

POWER.

At the outset of his presidential address to Section G (Engineering), Sir Alfred Ewing explained that it had to serve a double purpose, for it was also the Bramwell Lecture, delivered at this centenary meeting in fulfilment of a trust. Fifty years ago the late Sir Frederick Bramwell, who was then *pontifex maximus* in the world of engineering, had discussed the progress of mechanical invention at the jubilee meeting of the Association, and had prophesied that the internal combustion engine, then in its infancy, would displace steam as a means of producing power. In fifty years' time, he said, the steam engine would not be spoken of except as a curiosity to be found in a museum. Before his death he backed this opinion by giving the Association a sum to be paid as honorarium to a speaker who in 1931 should take this prophecy "as a sort of text" and deal with the then relation of engines of the two types.

Sir Alfred Ewing finds steam neither dead nor dying: on the contrary, it is actuating engines of vastly greater power than any that were even imagined when Bramwell spoke. But alongside of that we have wonderful achievements on the part of the internal combustion engine which go far to justify Bramwell's faith. Sir Alfred traced briefly the development of the internal combustion motor using liquid fuel, by Daimler, Diesel, and others; and went on to imagine Bramwell brought to earth again, "in an aeroplane, of course", to see for himself what had been accomplished. He would find, among many changes, his old haunt, the Athenæum Club, still a haven of rest for the mature, but now on the outer edge of a vortex of one-way traffic which made it difficult of approach —"a veritable inferno of internal combustion". Nevertheless, he would find steam continuing to do a great part of the work of the world both on land and water; and if he were taken to the Science Museum he would see there steam engines of a kind he never knew, enshrined not as relics of an obsolete past but as precursors of a modern era, the era opened to the world by the genius of Charles Parsons. Parsons's earliest steam turbine dates from three years after Bramwell made his prophecy. Since then the electric distribution of power has come on a big scale; and the work of power stations is almost wholly done by steam. Under modern conditions of high pressure and high temperature, steam furnishes the most economical means of generating power—except, of course, in countries favoured with hydraulic possibilities. In railway traction the dominance of steam is maintained, and electric traction—if it comes—will not affect that, for the central power stations will still use steam. On the roads the internal combustion engine is supreme, and a warm tribute is due to the constructive skill which has made such motors the convenient and reliable things they are.

In the field of ocean navigation, one finds sharp differences of opinion and of practice. For ships of the greatest size and speed, steam turbines are recognised as the best means of securing such a concentration of power as is essential. Many ships of a smaller type are driven by Diesel motors; but Sir Alfred doubts whether this preference is not, in part, a fashion that will pass. At the moment there is a distinct tendency to revert to steam, with, in appropriate cases, the use of pulverised coal.

In conclusion, Sir Alfred remarked that if we were to catch from Bramwell the mantle of prophecy we should be inclined to wear it ruefully. The cheerlessness of the present industrial outlook is in sad contrast to the heyday of Victorian confidence when Bramwell spoke. The world has learnt, through a severe lesson, that the gifts of the engineer are beneficial only if they are wisely used. They have brought obvious dangers through increasing man's ability to kill and to destroy. That is recognised, and now we are becoming aware of a more subtle social menace. We see the mechanised arts of production overreaching themselves, supplying commodities in a volume too great to be absorbed, and with a facility that tends to deprive man of his richest blessing—the necessity of toil. This raises problems, now conspicuously urgent, which the engineer, the economist, and the moralist must jointly set themselves to solve.

PRESENT POSITION OF ANTHROPOLOGICAL STUDIES.

In his presidential address to Section H (Anthropology) Prof. A. R. Radcliffe-Brown deals with the present position of anthropological studies. A realignment of these studies is taking place and should receive recognition. It is suggested that physical anthropology, which is largely confined to comparative racial anatomy, is due to be absorbed into a wider study of human biology which would include, besides physical anthropology and human palæontology, studies such as comparative racial physiology and psychology and human genetics. Prehistoric archæology has now become an independent subject, with its own special technique carried on by specialists. Its natural affinities are with history rather than with human biology or with sociology.

The science of comparative sociology differs from the older social anthropology in several vital respects. It rejects as being no part of its task the hypothetical reconstruction of the unknown past. It therefore avoids all discussion of hypotheses as to historical origins. It rejects all attempts to provide psychological explanations of particular social or cultural phenomena in favour of an ultimate psychological explanation of general sociological laws when these have been demonstrated by purely sociological inquiries. It endeavours to give precise descriptions of social and cultural phenomena in sociological terms, and to this end seeks to establish a suitable exact terminology, and seeks at the same time to attain to a systematic classification of those phenomena. It looks at any culture as an integrated system, and studies the functions of social institutions, customs, and beliefs of all kinds as parts of such a system. It applies to human life in society the generalising method of the natural sciences, seeking to formulate the general laws that underlie it, and to explain any given phenomenon in any culture as a special example of some general or universal principle. The newer anthropology is therefore functional, generalising, and sociological.

The new outlook in the study of cultures of non-European peoples involves the application of new methods both in field-work and in theoretical interpretation. The future of the subject lies with the field-worker. The day of the 'arm-chair' anthropologist is ended. The subject, however, suffers from the lack of anything like proper provision for research, and as the qualification for such research requires several years of special training and a great deal of special knowledge, the progress of the science is seriously hampered. What makes the situation almost tragic is that now, when by the gradual development of theory and the improvement of methods of investigation we are in a position to make the most important contributions to the science of man by the intensive and exact study of the less developed cultures of the world, those cultures are being destroyed with appalling rapidity. This process of destruction, through the combined action of European trade or economic exploitation, government by European officials, and missionary activity, is taking place with accelerated speed. Is there any other science, or has there ever been another science, faced with such a situation, that, just at the time it is reaching maturity, but while through lack of general interest and support it has few workers and very scanty funds, a great mass of most important material is vanishing year by year without the possibility of making any study of more than a minute fraction ?

Important developments in this branch of anthropology—the study of the cultures and languages of non-European peoples—are taking place as the result of the growing recognition of the fact that it can afford valuable and, indeed, indispensable aid in the practical problems of the government and education of dependent peoples. The British Empire, if it is to carry out with any honesty its self-imposed task of governing native peoples, must give much more support than it does at present to administrative anthropology.

BIOLOGICAL NATURE OF THE VIRUSES.

Dr. H. H. Dale's presidential address to Section I (Physiology) takes the form of an introduction to a discussion on "The Biological Nature of the Viruses", in which investigators of the virus diseases of plants are to join those whose studies have been concerned with the viruses infecting men and animals. He reviews briefly the history of the position of physiology in the proceedings of the British Association, and the steps by which it attained independent status in a section which has become responsible for bringing before the Association advances of fundamental knowledge over a wide field of medical and veterinary science ; and suggests that the biological nature of viruses, the discussion of which raises questions as to the lower limit of size compatible with organisation as a living cell and as to the possibility of life and self-multiplication without such organisation, is a proper concern of the physiologist.

An attempt to define the term 'virus' reveals three generally recognised characters: (1) invisibility with the microscope, (2) failure to be retained by bacteria-proof filters, and (3) failure to grow in the absence of susceptible living cells. A definition on these lines must include bacteriophages and the agents transmitting certain tumours, which satisfy all three conditions. Strict application, however, of a definition by such negative characters must narrow its scope with the advance of technique. Already methods of rendering some viruses visible have been found, and conditions permitting their growth on artificial media may at any time be discovered.

Some viruses have apparently been shown to consist of submicroscopic organisms; some physical measurements, on the other hand, suggest that the units of other viruses approach the dimensions of protein molecules in size, or are even smaller. If the agents classed as viruses are all of one kind, it seems necessary to doubt either the validity of some of the physical data or the identity with the virus of particles demonstrated by microscopical methods. If the view is accepted that some viruses, at least, are unorganised toxic principles in a state of molecular dispersion, their apparent power of self-production is without biological analogy. If the explanation is adopted that this is not a true self-multiplication, the toxic principle being reproduced by the perverted metabolism of the cell which it infects, the immunity acquired by an infected animal presents serious difficulties of interpretation.

With reference to the difficulty of attributing organisation to particles of the minute size indicated by certain physical measurements, it is suggested that viruses, as prepared for such examination, are not vegetative. The particles measured may be adapted only for transmission of the infective agent to cells in which it can resume vegetative life, and may therefore consist of material so densely aggregated that comparison of their size with that of heavily hydrated protein molecules affords no true indication of their possible complexity.

In conclusion, it is suggested that the new century of the British Association's history may give us an epoch of advance in knowledge of the viruses not less important than the epoch of discovery of the visible bacteria in the century now closing.

ON THE NATURE OF MIND.

In his presidential address to Section J (Psychology), Dr. C. S. Myers points out that conscious experience can only be enjoyed by the active 'self'—the 'individual' (that is, undivided) mental activity of the living organism—and that at its earliest stage conscious self-activity is differentiated merely into (*a*) 'acts' of the self and (*b*) 'modifications' of the self. The latter become differentiated afterwards into (i) feelings *of* the self and (ii) presentations *to* the self, that is, 'contents' of consciousness. Thus we reach the final stage of distinction between (1) *feelings*, (2) the conscious *acts* of apprehending, recalling, deciding, inferring, etc., and (3) *what* is consciously apprehended, recalled, decided, inferred, etc. The last, the contents of consciousness, are, Dr. Myers suggests, the *un*conscious acts of relatively lower mental levels, which become *conscious* presentations to the self when they are accompanied and received by the self-activity of the highest mental levels.

The self is the highest controlling and directing power within the organism. Its direction, once consciously started, may be continued unconsciously: we may consciously but vainly try to recall some past experience or to solve some difficult problem; and after our giving up the effort, this directive activity may still persist unconsciously, until suddenly the forgotten object or the abandoned solution suddenly flashes full-born and unbidden into the self's consciousness. But purposive activity need not *originate* in self-activity: the inspirations of genius and the intuitive judgments and decisions which, crude as they are before submission to the self's judgment, arise apparently from the unconscious 'depths' of the mind with impulsive force and compelling conviction, afford striking examples of this fact.

The self implies a wide sphere of activity rather than a punctate, pineal gland-like soul. We cannot hope to localise any act of consciousness or any conscious content or feeling in some small region of nervous substance. Because vision ceases when the *area striata* in the occipital region of the cerebral cortex is destroyed, we are not justified in saying that this area is the *seat* of our visual consciousness. All that we are warranted in saying is that it is *essential* for our visual consciousness, that without it vision is impossible—a very different statement. It is impossible to localise consciousness. The higher forms of mental activity have a generalised localisation: even where 'essential' areas can be mapped out for lower conscious processes, such cortical localisation is only relatively definite, and other areas may in some cases assume the function of any particular area when the latter has been destroyed.

The fundamental purpose of consciousness is the preservation of the organism by guidance and direction, by the formation and satisfaction of ends and values. On the physical side, we can form no conception of that activity, throughout life and mind, which distinguishes evolution from the blind running downhill of a wound-up mechanism. We can at present find no metabolic basis for creative, directive activity; it appears, however, as if mental work makes far greater physiological demands than it should, according to the purely physical considerations of mechanical energy.

Both mechanical and directive activities are essential to conceptions of the struggle for existence and the conservation of the self. Mental activity involves the quintessence of the non-mechanical directive activity of life; and consciousness is but that activity raised to its highest power, limited to the highest level of psycho-neural activity—the self.

THE ADVANCEMENT OF BOTANY.

In the first part of his presidential address to Section K (Botany), Prof. T. G. Hill gives a historical outline of the development of botany since 1831, and then considers present and future needs and policy, thus introducing a discussion on the training of botanists for economic and industrial positions.

The year 1831 marks the beginning of a threefold epoch in botany: the search for a natural system of classification; the emergence of morphology as a study separate from taxonomy; and the development of physiology. To the first, Great Britain contributed a full share; but in anatomy, morphology, and physiology, the tale of British activity during the succeeding fifty years, despite the brilliant lead given by Grew, Hales, and Knight, is indeed dismal. Against a battalion of continental workers we can barely range a section.

The brilliant generalisations of Charles Darwin, however, were an outstanding contribution to botany. The reasons for our deficiencies during this period (1831–1882) are patent. The classical traditions of our old universities dominated teaching, with the result that the approach to biology was, in the main, through medicine; botany was, indeed, of the faculty of medicine rather than of science, and the majority of British botanists were qualified medical men. Other reasons lie in the facts that the period was one of exploration, expansion, and development of the Empire, which meant a great inflow of plants for identification, and the labourers were few. Finally, the systematists did not entirely favour the new movement, and if not actively antagonistic, they looked upon it with amused tolerance.

The botanical renaissance in Great Britain began about 1875 and it happened in the Royal College of Science. The credit for it is due to Thiselton-Dyer, who, as Huxley's demonstrator, instituted and conducted the first laboratory classes in botany. The advance was accelerated by the translation of the great German text-books, and the University of London gave powerful aid by the high standard of its examinations and its insistence on practical tests. The volume and importance of British work in all branches of botany gradually increased and expanded in various directions: to take but two examples, the re-discovery of Mendel's work inspired a period of intensive investigations on plant breeding and certain aspects of metabolic physiology and cytology, whilst the development of ecology greatly stimulated the study of taxonomy, causal morphology, and physiology.

Notwithstanding past experience, it required a great war to force the lessons home that man is dependent on the green plant, and that the sustenance, development, and co-ordination of science is a prime necessity in the government of the modern State. These lessons were remembered when peace came, with the result that the systematised investigation of botanical problems became a settled policy not only with us but also with other nations. The immediate effect is a gross over-production of many essential commodities, which has caused a tendency in States and industries to curtail expenditure on research and expert advice. This is a wrong policy, for it is in times of economic depression that research is most essential. In Great Britain many of the problems involved are investigated in numerous research stations, old and new. In them lurk a few dangers: applied research can be over-organised; the tendency to justify their existence may tempt newly founded institutions to disseminate unripe fruit; and the value of pure research may be obscured. These dangers, for the most part, will be eliminated if there be co-operation between the applied workers and their academic brothers, which can be effected by a close connexion between the botanical departments of universities and research institutions, accompanied by an occasional exchange of the workers in both.

The British Commonwealth of Nations is, in the main, an agricultural empire; the need for trained botanists for administrative and technical service is patent: the problem is their supply and their training.

EDUCATIONAL DEVELOPMENT, 1831–1931.

Sir Charles Grant Robertson, president of Section L (Educational Science), in his presidential address disclaimed his ability to defend a subject more vulnerable even than theology to the charge that " whatever is true is not new and whatever is new is flagitiously and demonstrably untrue ". He dated the beginning of the reform movement with Castlereagh's death in 1822, emphasising three general points: first, the influence of the utilitarian group (the Benthamites); secondly, the Oxford movement started by Keble's sermon in 1833; and, thirdly, the organised and widespread campaign against ignorance, leading to the foundation in 1827 of the Society for the Diffusion of Useful Knowledge. But the fundamental question remained open: to whom was the duty of education to be left—to the individual conscience of the parent, to the Church as the depository of Christian truth, or to the State, with a compulsory power and the right to represent the civil mind ?

The years from 1825 to 1840 were devoted mainly to discussion, and the following thirty years, ending roughly in Forster's Education Act of 1870, to Royal and Governmental commissions. This period saw the revolution in public school education associated with Arnold of Rugby, Kennedy of Shrewsbury, Thring of Uppingham, and Haig-Brown of Charterhouse, and saw also the nineteenth century ' renascence of science ' inspired by Faraday's discoveries. That scientific renascence acknowledged both the importance of science as knowledge and its vocational or utilitarian value, but also, under the inspiring leadership of Huxley, " the Achilles and protagonist of the twenty years' battle for the capture of the classical Troy ", its " cultural indispensability ". Sir Charles referred also with feeling to another renascence—the education of girls and women—paying homage to the work of Frances Mary Buss, Dorothea Beale, and Sarah Emily Davies.

The Forster Education Act of 1870, though marking the culmination of a long period of effort and controversy, is not regarded by Sir Charles " as a revolutionary or a creative measure in the true sense of the term ". It made no attempt to correlate elementary and secondary education. It was a compromise. No Government from 1831 to 1931 had tackled fairly and squarely the so-called religious issue, " because a courageous solution of it would be unlike successful operations in surgery; the operation would succeed, the Nation would recover, and the operating surgeon, the Minister, would die ".

Proceeding, Sir Charles invoked a Rip Van Winkle who, having slept through the century under review, wakes to discover the new science of psychology. After commenting somewhat caustically on this new science, Rip Van Winkle remarks, " I observe with immense interest that after a hundred years you are still arguing precisely all the fundamental questions that perplexed us ". But, as Sir Charles said, the science of psychology is only in its infancy. It may be possible in future to define the limits of educability and to come to an understanding of " the functional differentia between the sexes ".

Concluding, Sir Charles acclaimed the social revolution, largely due to the educational progress of the last hundred years, steadily regrading and reshaping the whole Commonwealth that we call the British Empire.

THE CHANGING OUTLOOK IN AGRICULTURE.

Sir John Russell, in his presidential address before Section M (Agriculture), directs attention to the fact that agriculture as an art was already far advanced when the first meeting of the British Association was held in 1831. The great improvers of the eighteenth century wove the new crops into a rotation which provided both animal and human food, and was indeed the best system the world had yet seen, but it was in 1831 entirely empirical. Scientific work was, however, beginning, and round about 1840 three important events occurred: Liebig published his epoch-making essay on the application of chemistry to agriculture, Lawes began the famous Rothamsted experiments which almost at once led to the founding of the artificial fertiliser industry, and the Royal Agricultural Society began its beneficent work of fostering the application of science to practice. Economic conditions favoured the growth of the home agriculture, there was no serious competition from overseas, and from about 1850 until 1890 British agriculture flourished; it attained a high standard of technical excellence, it was financially successful, and it supplied the country with most of the food required. Then within a few years it collapsed. The chain of transport arrangements with the United States and Canada was completed and farm produce came on to our markets at prices with which British agriculturists could not possibly compete. The overseas systems were inferior to our own in production per acre, but the shortage of population necessitated the development of labour-saving machinery, so that the production per man was greater, and this higher efficiency of output won the day. British farmers suffered greatly; many became bankrupt.

Gradually it was realised that the way out of the difficulty was to specialise: to aim at producing, not everything needed, but the things that could be produced best and most easily; and this specialisation favoured the application of science to agriculture. From 1889 onwards, when the Board of Agriculture was founded, agricultural colleges began to grow up; about 1900 the system of county organisers was begun; and in 1909 the Development Fund was set up, out of which agricultural research was financed. A wise administrative policy has always been followed by the Commissioners, and probably no public money has ever been better expended. The relations between the scientific workers, the farmers and the Commissioners, and the Board of Agriculture have always been of the happiest, and as a result of this collaboration agriculture steadily improved and in less than twenty years after the deepest depression it had regained a considerable degree of quiet prosperity.

Then came the War, during which the whole civilised world strove to improve agricultural production. After the War the full force of the improvements was felt, and it was found that the world's power of producing food was far in excess of the power of consumption. There has therefore been a great fall in prices, and agriculture is once more in a state of deepest depression. The chief factors in the new situation have been the development of plant genetics, which has led to the production of new varieties of plants specially adapted to particular regions; improved methods of controlling insects and parasites; the internal combustion engine; and refrigeration. Many regions of the world which in 1840 were waste, and could be nothing else, are now closely cultivated and dotted with homesteads.

The problem now before the agriculturists of the world is to organise their production on a contract basis, so as to supply the world's need of food with a reasonable margin of safety, but without the excess production which benefits no one and only injures themselves.

Printed in Great Britain by R. & R. Clark Limited, Edinburgh.

wonderful applications have grown out of Faraday's discovery when he produced electricity without actually putting bodies in contact. Dr. Elihu Thomson, the pioneer electrical engineer who invented electric welding, laid stress on the development of electrical power from Faraday's original conceptions. Prof. P. Debye showed the importance of Faraday's work for physical chemistry and the molecular theory of matter; while Prof. P. Zeeman paid tribute to Faraday's genius in conceiving a possible connexion between magnetism and light. The great physicist failed in his attempt to prove his hypothesis from lack of effective apparatus: Prof. Zeeman succeeded many years afterwards, and thus gave his name to the remarkable 'effect' of two magnetic poles on a source of light placed between them. Lord Rutherford referred to the importance of the discovery of the laws of electrolysis by Faraday, whom he honoured as a master in experimental work.

It was left to Sir William Bragg, the present holder of Faraday's position at the Royal Institution, to deliver the commemorative address of the evening, in which he surveyed the remarkable discoveries of his predecessor, explaining their history and meaning, and showing how they illustrate his genius and his character. In his concluding address, the Right Hon. Lord Eustace Percy, M.P., president of the Royal Institution, pointed to the noble example of Faraday as an incentive for scientific education and research. It was by the courtesy of Sir John Reith and the British Broadcasting Corporation that the season of promenade concerts was interrupted to enable the Faraday Commemoration Meeting to be held in the Queen's Hall. But it was befitting to Faraday's memory that the nation and the world at large were able to follow by wireless these celebrations. The following day, Sept. 22, the Institution of Electrical Engineers held a conference at the Kingsway Hall on "The Place of Electricity in Transport, Communications, and the Household", which was attended by a large number of distinguished men of science and the delegates and guests to the centenary celebrations. Sir Josiah Stamp, Mr. J. S. Highfield, Miss C. Haslett, Mr. Ll. B. Atkinson, Sir Oliver Lodge, and Mr. C. C. Paterson, president of the Institution, outlined in turn the bearing of Faraday's discoveries on the amazing developments of modern electricity.

In connexion with the Faraday centenary celebrations, a short talking film, presenting a few simple points concerning Faraday and his discoveries, has been made by the British Thomson-Houston Co., Ltd., and given to the Faraday Centenary Exhibition Committee of the Institution of Electrical Engineers. It has been shown at the Marble Arch Pavilion since Tuesday, Sept. 15, and will be included in the programmes of a large number of cinema theatres throughout the country during the next few weeks. In the production of the film the British Thomson-Houston Company was fortunate enough to enlist the co-operation of Sir William Bragg as narrator, and the audience is thus enabled to see and hear one of Faraday's most eminent successors.

Beginning with a reference to the humble origin of Faraday and his studies as a youth, Sir William Bragg shows in the film the manuscript book in which Faraday wrote out his account of Davy's lectures, and tells how he came to be engaged at the Royal Institution. Tracing his work further, he then shows the part of the "Diary" in which Faraday recorded his epoch-making experiment of Aug. 29, 1831; and after this comes a demonstration by "Faraday himself" with his famous iron ring and the magnetic needle. Then by means of more modern apparatus it is explained how magnets and coils, moving relatively to one another, lead to the production of currents, and reference is made to the experiments with iron filings and Faraday's ideas of lines of force. The connexion of these things with modern electrical development is explained, and the film ends with a series of pictures of electric trains, telephone exchanges, factories, giant magnetic grabs, and X-ray apparatus. The film will, we think, be appreciated by all who have read anything of Faraday's life and work, but it is probable that, in spite of Sir William Bragg's interesting talk, the film is too short and the action too rapid for it to leave any clear impressions on the minds of those unfamiliar with electrical discovery.

Referring to the article "Faraday's London Friends", in Nature of Sept. 19, Mr. T. E. James writes: "Perhaps, after all, the best friend of Faraday was the sympathetic individual, generally referred to as 'a Mr. Dance'—meaning the member of the Royal Institution who either gave tickets of admission or took Faraday in 1812 to hear four of the last lectures of Sir Humphry Davy. It has been possible to identify him as William Dance, who lived at 17 Manchester Street, London. He was born in 1755 and died in 1840. He was a son of James Dance, dramatist and actor with the stage name of Love, who was educated at Merchant Taylors' School and St. John's College, Oxford, leaving the latter before graduation. William Dance was a musician and composer; in 1813 he helped in the establishment of the Philharmonic Society, and acted as its treasurer. He was a brother of Commodore Sir Nathaniel Dance, whose strategic exploit with a French man-of-war in 1804 was the talk of the day."

To the man of science, discovery and the interpretation and correlation of discoveries are his ultimate aim. They mark an end in themselves; whereas to the industrialist such discoveries are only a means to an end, his ultimate aim being the exploitation of discovery and its application to industry. Perhaps there is no example quite so notable as that of Faraday's discovery of a century ago. It marked the inception of an industrial revolution which is still as active and progressive now as it has ever been. The development of electric lighting and power has attained such dimensions that the amount of capital invested in it throughout the world exceeds £5,000,000,000. The substitution of tungsten filament lamps for the old carbon filament in 1908 involved an annual world saving of nearly £50,000,000. Now, in this present stage of the electrical revolution, there are, apart from tube lines, more than 555 route miles of electrified railway in Britain; 200,000 tons of aluminium are produced annually by electrolysis; the 'grid' was brought into use in Great Britain in 1930, and when it is finished, at an approximate cost of £30,000,000, will supply cheap electricity to the country; and electric generating plant of the world has reached nearly 100,000,000 kilowatts. The present flood-lighting, too, is but another portion of the immense superstructure of invention which has been erected upon the foundation of Faraday's research. Such information is admirably presented in the *Times* "Faraday Number", a collection of splendid tributes to Faraday's memory from a number of eminent men of science, published on Sept. 21. The utilitarian value of science is well illustrated in the number; but, perhaps unconsciously, the supplement brings home the historical significance of this centenary and the ethical and cultural value of science, apart from its practical use.

In the *Scientific Monthly* for September, Edith W. Stone writes an interesting article on Joseph Henry, the American physicist. His grandfather came from Scotland and changed his name from Hendrie to Henry. Henry was born in Albany, New York, in 1797, but stayed with an uncle at Galway, Ireland, from an early age until he was fifteen, when he returned to his mother at Albany. He was apprenticed to a watchmaker, but improved his knowledge by attending night classes. When twenty-eight years of age, he was appointed professor of mathematics at Albany Academy. It was during this period that he began to study and perfect the electromagnet. In 1832, Henry was appointed professor of natural philosophy at the College of New Jersey (now Princeton). He was the first secretary of the Smithsonian Institution, a position which he held until his death in 1878. The author points out the many points of resemblance between Faraday and Henry. Both were gentle and unassuming, yet deliberate and persistent, and each was filled with an unswerving and lifelong devotion to scientific research. That Henry was an independent discoverer of the fundamental fact of electromagnetic induction is not now disputed. Faraday, however, was the first to make public his discovery. Henry is reported to have said: "I ought to have published earlier, but I had so little time. I desired to get out my results in good form, and how could I know that another on the other side of the Atlantic was busy with the same thing?" His memory has been kept green by calling the unit of self-induction the henry.

"History", declares Prof. H. E. Armstrong, writing in the *Pharmaceutical Journal* of Aug. 29, on the dyestuff industry, "when you can test it, is more often than not perversion of fact." This is a characteristically hard saying, but Prof. Armstrong's contribution to the early history of that industry does not thereby lose anything in credibility or interest. We are bidden by an observant and critical contemporary to regard Perkin as the originator, but not as the founder, of the British industry. "Perkin did a giant's work and set a giant's example, but he only started the ball rolling. Hofmann, he, and Nicholson were a noble triumvirate; they together made the industry." We failed to develop it "just simply through lack of intelligence". Here is another hard saying; one which is easy to resent but difficult to refute. In such an industry strength and vitality were the fruits—in Germany—of scientific control, of shrewd business ability, and of an intelligent, inquisitive outlook based on wide training in scientific method; so the first prize went to the strong.

The interest of Prof. Armstrong's observations lies particularly in their contemporary origin, but their importance depends on the fact that at this time of crisis they lead us to the root of things. To say that we need in our industrial life a greater measure of scientific direction and of scientific control is merely to say that we ought more often to base our actions upon that exact knowledge which could be, but may not have been, ascertained, and that we should less frequently be guided by guesswork; not that we shall necessarily escape our present difficulties by building a new laboratory, but that we should gain by giving greater authority and employment to intellects trained in the use of the methods of science. "To play the game successfully," says Prof. Armstrong, "management must be in technically competent hands, not of politicians; full support of users must be secured: unless users and producers can be led to see eye to eye the industry will soon be again lost to us. The great danger before us is over-organisation—so-called rationalisation—with its consequent elimination of individuality and talent and lessening of employment."

Although the meteorological records for August received by the Meteorological Office showed that for almost all parts of England the month was a wet one, the figures for the different districts expressed as a percentage of the average were not such as to make the month so remarkable as some others of recent years. Apart from the Channel Islands, the largest excess was 84 per cent for the south-east of England, the Midlands and eastern England following with 57 and 52 per cent respectively. The feature that was most notable was the number of exceptional downpours in limited areas. Some of these were associated with thunderstorms in a sultry spell early in the month, but many occurred in one or other of the windy, cyclonic, and almost wintry spells that followed. Examples of the former were furnished by a fall of 113 mm. in one and a half hours at Langford, Salisbury, on Aug. 4, 74 mm. near Petersfield in about an hour on Aug. 5, and 56 mm. at Greenwich in a short time on the same date. Heavy cyclonic rains include 82 mm. at St. Heliers, Jersey, on Aug. 24, 72 mm. at Cromer on Aug. 8, and 51 mm. at Tynemouth on Aug. 19. Many of these downpours represented the equivalent of a month or more of normal rainfall and gave rise to flooding. Monthly totals were seldom of such exceptional character, but mention may be made of St. Heliers, 214 mm., which is three and a half times the average, and of the total of 200 mm. at Oldham Road, Manchester. In contrast to these, Lerwick had only 5 mm. altogether; for Scotland and Ireland generally there was a deficiency compared with the average.

IT is not often that we hear of West Indian hurricanes visiting British Honduras, but the records of former years show that at long intervals one of these storms, like that which devastated Belize on Sept. 10, has travelled sufficiently far west in a low enough latitude and has at the same time been late enough in recurving northwards to strike that colony. The track followed in the recent hurricane, or one closely resembling it, is shown as a recognised though abnormal one in some works dealing with West Indian hurricanes. The storm of Oct. 12–18, 1916, crossed the colony only slightly farther north. If the statement, made in certain newspapers, that another cyclone followed the recent one along a not far distant track is correct, then there is the curious coincidence that the visitations of 1916 and 1931 were both cases of hurricanes occurring in pairs. In 1916, the later of the two appears to have been the more destructive. It passed directly across Pensacola, Florida, giving rise to winds of 120 miles an hour, fortunately with little or no loss of life, though at an earlier stage it caused a vessel to founder with the loss of twenty lives. In the present year, reports received so far indicate that the first-comer was the more violent; it is possible, however, that the second was not less violent, but did not cross any thickly populated district.

THE annual Exhibition of the Royal Photographic Society was opened on Sept. 11, and will remain open until Oct. 10. As usual, the principal part of the exhibition is pictorial, but there is also a considerable amount of material of scientific interest. The variety of subjects is very large, and it is only possible here to notice a few exhibits. The Safety in Mines Research Board shows an admirable series of photographs of flames in combustible gases moving between the plates of a condenser. With the condenser uncharged, the flames are seen to move symmetrically from the point of ignition; with the plates charged, the movement is directed towards the cathode. In the national history section, Dr. W. D. Walker has been awarded the Society's medal for a series of photographs of the life-history of the kangaroo from birth to maturity; many will be surprised to note that the kangaroo at birth is less than an inch in length. Herr Karl Stülcken shows a series of somewhat similar nature illustrating the development of the peacock butterfly through its various stages of life. Many of the exhibits this year are interesting especially in relation to medicine and surgery. Several examples of the cure of rodent ulcer are shown, but the most striking exhibit in this field is, perhaps, that of two negatives taken inside a stomach by means of a tiny stereoscopic pinhole camera. In order to take the pictures, the camera, with a small lamp attached, was swallowed by the patient.

THE eighth International Congress of Photography took place at Dresden on Aug. 3–8. It is significant that at its closing session the Congress adopted for itself a new name: The International Congress of Scientific and Applied Photography. At the previous Congress, held in London in 1928, an attempt was made to include pictorial photography, but at Dresden there was no time to consider anything but science in relation to photography. Altogether, eighty-two papers were communicated. These will be printed in one volume shortly, and will form a very valuable record of many of the scientific researches carried out during the past three years all over the world. Many of the papers dealt with problems of cinematography and sound-recording on film. These applications of photography have made great demands for an increased accuracy of control in the processing of film, and have necessitated exhaustive researches into the behaviour of sensitive materials under high intensities, which previously had not been much studied.

THE problems of standardised sensitometry were again brought forward before the Congress, and agreement was reached concerning a standard light source for testing negative materials. The proposals are those put forward from America in 1928, and a great deal of credit is due to Messrs. Gibson and Davis, of the Bureau of Standards in Washington, for the careful working out of a series of light filters for producing artificial daylight from various primary sources of light. There still remains much in sensitometry which needs standardisation, and the Dresden Congress will perhaps be notable by reason of the German proposals for standardised testing of commercial products. These were put forward tentatively and will be investigated by the various national committees on sensitometry before any general action is taken. The application of 'H and D' numbers to the evaluation of sensitivity has been attacked very much during recent years, and it may well be that a new basis for 'speed' evaluation will eventually be adopted. One of the evening lectures delivered to the Congress was by Dr. Goldberg, who dealt with the subject of photoelectric cells in recording. The Royal Photographic Society is fortunate in having secured Dr. Goldberg for the Traill-Taylor Memorial Lecture, which is to be given on Oct. 27, at the Society's rooms at 35 Russell Square, W.C.1, at 7 P.M. Dr. Goldberg will again deal mainly with the subject of photoelectric cells.

A NEW Scottish centre of economic and industrial study and research will be inaugurated at Dundee on Friday Oct. 2, when the School of Economics and Commerce is to be opened by Sir Josiah Stamp. The School owes its foundation to the liberality of a prominent leader of the jute industry, Mr. George Bonar, who desired to make available better facilities for higher education in economics and commerce. According to the deed of gift, the courses of instruction are to be of university standard, and the School will aim at preparing its students for responsible administrative and professional positions and providing opportunities for educational advancement to those already engaged in industry. To this end, three different courses of instruction are offered by the School. To graduates of approved universities it offers a one-year post-graduate course; to other qualified students it offers a two-year course; and to students already engaged in industry it provides facilities for evening study. The Principal of the School is Dr. J. A. Bowie, formerly director of the Department of Industrial Administration in the College of Technology, Manchester.

A CHARACTERISTIC of the malignant tumours known as sarcomata is the richness of their blood-supply; frequently even the thin lining membrane of the blood-vessels is absent, so that the sarcoma cells lie in direct contact with the blood-stream and are very liable to be swept away to distant parts of the body. They should, therefore, be susceptible to the toxic influence of therapeutic agents injected into the blood-stream. Positively-charged colloids, injected intravenously, will cause precipitation of the negatively-charged blood proteins; hence it is safe to use only negatively-charged colloids, which, moreover, might react with the basic substances of the cell nucleus and so alter the metabolism of the cell. A. C. Hendrik and E. F. Burton have, therefore, tried the therapeutic effects of a non-toxic colloidal solution of metallic arsenic, in which the particles are negatively-charged (*Canad. Med. Ass. Jour.*, vol. 24, p. 642; 1931). Four cases of bone tumour were selected for the treatment, and the progress after infection was followed radiographically; in two of them deep X-ray therapy was also given. The results in all cases were encouraging: calcification and ossification of the tumour occurred and the bone destruction was retarded or inhibited. The solution was also administered to some patients suffering from carcinoma: the young undifferentiated cells of the tumour appeared to be destroyed; in bone sarcoma this destruction is succeeded by the deposition of calcium, enabling progress to be followed radiographically.

IN a series of papers contributed to the *Electrical Times* during August and September, J. C. Wigham gives an interesting account of the progress Russia is making in industrialisation by the five years plan. Before the War, Russia was largely an agricultural country exporting wheat, timber, and oil. After the revolution, owing to internal disorganisation, the country became too poor to pay for manufactured articles from outside. The Soviet Government therefore decided three years ago to erect industrial plants in Russia to manufacture the goods formerly imported, so as to make Russia economically independent. Amazing progress has been made. The first part of a huge furnace plant at Magnetogorsk, capable of turning out three million tons a year, is expected to be ready by Oct. 1. In about a year's time the Ford plant at Nijni Novgorod for building 140,000 motor cars a year will probably be completed. The outfit brought from America is beginning to be assembled and complete cars will soon be manufactured. At Stalingrad a tractor plant designed to manufacture 50,000 tractors a year is already at work. It is not quite clear how the management of these works is to get the requisite staff of skilled and unskilled workmen. Most of the workpeople employed, men and women, boys and girls, have up to a few months ago been working on the land or as skilled or unskilled labourers in industries other than engineering. The immediate provision of trained skilled workmen is almost an insuperable problem, as training for a new industry always takes time. If the production of these great factories is not carefully balanced, there will be over-production and the unwanted surplus will be sold abroad at any price it will fetch. Good progress has been made in developing electrical power plants and in some other engineering schemes, but the railways are behindhand and the coal mines are said to be poorly equipped.

THE first congress of the Section of Preventive Pædiatrics of the Save the Children International Union of Geneva was held at the Hague on Sept. 7–8, under the presidency of Prof. G. Scheltema, of Groningen, and was attended by members of fourteen different countries. The subjects for discussion were: the mortality during the first ten days of life and its prevention, introduced by Prof. P. Lereboullet and Dr. Lacomme, of Paris, and Prof. A. Schlossmann, of Düsseldorf, and return cases of scarlet fever and their prevention, introduced by Prof. F. von Groer, of Lemberg, and Dr. A. Lichtenstein, of Stockholm. The British representatives who were invited to take part in the discussions were Dr. H. Chodak Gregory, who dealt with neo-natal mortality, and Dr. J. D. Rolleston and Dr. B. Schlesinger, who discussed return cases of scarlet fever. The next congress will be held at Geneva in July 1932.

THE details of the programme for the symposium on the British fuel problem, to be held in the Great Hall, the University, South Kensington, at 10 A.M. on Monday, Sept. 28, in connexion with the meeting of Section B (Chemistry) of the British Association, have now been settled. The symposium will take the form of three addresses in simple and non-technical language. Sir David Milne-Watson, the governor of the Gas Light and Coke Company and the president of the Institute of Fuel, will talk on coal, Sir John Cadman, the chairman of the Anglo-Persian Oil Company, on oil, and Mr. H. T. Tizard, Rector of the Imperial College, South Kensington, on future possibilities.

WE much regret to announce the following deaths: Prof. Percy Groom, M.B.E., F.R.S., formerly professor of the technology of woods and fibres at the Imperial College of Science, on Sept. 16, aged sixty-six years; Sir Howard Grubb, F.R.S., scientific adviser to the Commissioners of Irish Lights, and widely known by his construction of astronomical telescopes and other instruments, on Sept. 16, aged eighty-seven years; Prof. David Starr Jordan, emeritus chancellor of Stanford University, California, formerly president of the University, who was an authority on fishes, aged eighty years; Dr. Joan Proctor, curator of reptiles and amphibia to the Zoological Society of London, on Sept. 20, aged thirty-four years; Sir William Simpson, C.M.G., who was director of tropical hygiene at the Ross Institute, Putney, and editor of the *Journal of Tropical Medicine*, on Sept. 20, aged seventy-six years.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Angular Momentum of Light.

THE work of Compton on X-ray scattering led to the general acceptance of the idea that the scattering of radiation by a material particle is a unitary process in which energy and linear momentum are conserved. A molecule is, however, a much more complicated structure than an electron, and the conservation principles by themselves would give us an erroneous idea of what we should expect in light-scattering. This follows from the fact that a molecule has in general three degrees of freedom of rotation, several degrees of freedom of vibration according to its complexity, and various possible modes of electronic excitation, and that each of these may correspond to one or other of an extended series of quantum numbers. Restricting ourselves to the cases in which the molecule takes up a part of the energy of the quantum, the conservation principles would indicate that the spectrum of the scattered light should contain an immense number of new lines.

Actually, a remarkable simplicity characterises the observed spectra of the light scattered by polyatomic molecules, a simplicity which is in striking contrast with the complexity of their absorption and emission spectra. It is clear that the Compton principles cannot be regarded as capable of *predicting* the observed phenomena of light-scattering, and that their utility lies solely in the *interpretation* of results discovered by experiment. These remarks seem necessary to correct an impression to the contrary which finds expression in some recent publications.

We may extend Compton's principle and add angular momentum to the quantities which we should expect to find conserved in the collision between a light-quantum and a molecule. The fact that, in liquids and solids, the mutual influence of the material particles is very considerable, attaches some uncertainty to the interpretation of the results obtained with them. The recent success of Bhagavantam at Calcutta in measuring the polarisation and intensity of light scattered by gases, however, opens up new possibilities for the development of the subject.

As a working hypothesis, we may follow Dirac and assume that the angular momentum of a photon is *plus* or *minus* $h/2\pi$, intermediate values being inadmissible. This supposition enables us to interpret very simply the known selection rule $\Delta m = 0$ or ± 2 for the change of rotational quantum number of a diatomic molecule in light-scattering, which follows as a natural consequence of it. Further, it follows[1] that a change in rotational quantum number of the molecule should be accompanied by a reversal in the sign of circular polarisation of the photon, when the latter is scattered in the forward direction. This reversal has been actually observed by Bär and by Bhagavantam with the rotational wings accompanying the original mercury lines scattered in liquids, and the data obtained by Bhagavantam with hydrogen gas may also be interpreted as a confirmation of the same result.

It is remarkable that the latter result is also predicted by the classical electromagnetic theory of light for the case of a rotating anisotropic particle scattering circularly polarised radiation. Nevertheless, it is clear that the observed phenomena may be regarded as an experimental proof that radiation has angular momentum associated with it, and that it has the values $\pm h/2\pi$ for each quantum.

The Penetration of Light through Successive Layers of Tissue Paper.

IN a letter to NATURE,[1] J. R. Ashworth mentioned the use of a stepped wedge of fine quality tissue paper in describing a method of measuring ultra-violet light from the sky, photographically. In a later issue,[2] P. W. Cunliffe pointed out that "a step wedge constructed of a diffusing medium, such as thin tissue paper, does not obey the logarithmic 'law', which is valid only for transparent media". It so happens that I obtained data last spring which bear on this subject.

Mr. G. M. Spooner, working on phototropism, was desirous of reducing illumination by steps, and used sheets of tissue paper for the purpose. The alteration in the intensity of diffuse daylight was measured, using a vacuum sodium photoelectric cell, covered with a double surface flashed opalised-glass plate. The combination has a maximum sensitivity in the violet or near ultra-violet. The results are shown in the table.

No. of sheets	Series A.	Series B.	Transmission per cent.	B (calc.)
1	67·0	69·5	..	..
2	48·7	52·5	75·5	55·0
3	..	40·1	76·4	43·5
4	29·1	30·8	76·8	34·4
5	..	25·3	82·1	27·2
6	..	19·7	77·9	21·5
7	..	16·2	82·3	17·0
8	..	12·8	79·0	13·5
9	..	10·4	81·3	10·7
10	..	8·4	80·8	8·4
			Mean 79·1	

The calculated values in the last column were obtained by using the mean percentage transmission, 79·1 per cent, and multiplying the Series B value for one thickness, namely, 69·5 per cent, by it, to obtain the amount transmitted by two thicknesses, and so on to the tenth.

It may be seen that the calculated and observed values agree well, when allowance has been made for the extra loss by reflection and scattering at the first surface. This amounts to 9·6 per cent. The transmission coefficient appears to increase somewhat with increasing numbers of sheets, at the start. This is probably due to heavy absorption of the shortest wavelengths, which are thus eliminated.

Analysis of Complicated Band Spectra with the Aid of Magnetic Rotation Spectra.

THE absorption spectra of polyatomic molecules are usually so complicated that an analysis of their rotational fine structure seems impossible. We have therefore tried if the magnetic rotation spectra which are obtained by putting the absorbing gas in a magnetic field between crossed nicols[1] will not simplify those spectra sufficiently so that an analysis becomes possible. It was found that with NO_2 a remarkable simplification occurred. But in this case also the simplified magnetic rotation spectrum is very complicated and we have not yet succeeded in analysing it, further experimental work under higher dispersion being required before an analysis can be attempted.

With NO_2 in a bulb of 3 cm. in diameter at rather low pressure (only slight trace of yellow by transmitted light), a rotation spectrum appeared with a field strength about equal to that of an ordinary permanent magnet. As the field increased, some of these lines disappeared and new lines were developed. The disappearance seems to be a real phenomenon, and not due to a 90°-rotation, as observations with the double quartz wedge of *R*- and *L*-quartz indicated that the rotations involved were of only a few degrees.

In order to clarify the situation and illustrate better the theoretical significance of the magnetic rotation spectra, we studied some diatomic gases, in which case two different conditions are possible: (*a*) at least one of the states involved in the transitions has a magnetic momentum, or (*b*) neither initial nor final state have a magnetic momentum (for example, $^1\Sigma \rightarrow {}^1\Sigma$ transitions).

The amount of the magnetic rotation of an absorption line is determined by its Zeeman effect. If there is a magnetic momentum, it is, except for abnormal cases, along the internuclear axis. In this case there is an appreciable Zeeman effect only for the lower values of the rotational quantum number, as the rotation disturbs the orientation of the magnetic moment in the external field. Accordingly, we should expect in the magnetic rotation spectrum excited by low fields with appreciable intensity only lines which arise from such levels. In higher fields new lines with higher values of the rotational quantum number will appear. An example of such a case is furnished by Na_2, the magnetic rotation spectrum of which has been used already by Loomis [2] for the vibrational analysis of the absorption spectrum. We photographed it with varying field strengths. It behaves exactly in the way indicated above.

If neither the initial nor the final state of the non-rotating molecule have a magnetic momentum, there would be no Zeeman effect, and accordingly no magnetic rotation, if the molecule could be considered as being entirely rigid. (A possible influence of the nuclear momenta is evidently too small.) But by its rotation the molecule is deformed, and this deformation can usually most easily be described as a decoupling of the orbital nomentum from the internuclear axis. A magnetic momentum in the direction of the *rotational* axis is thus produced, which may cause a magnetic rotation of the lines in question. But contrary to case (*a*), the lines with *higher* rotational quantum numbers will be chiefly affected.

We have such a case in the absorption bands of Br_2 and I_2, which are both $^1\Sigma \rightarrow {}^1\Sigma$ transitions. The magnetic rotation spectrum of these gases shows indeed a striking difference from the magnetic rotation spectrum of Na_2. Instead of showing only a few lines, it yields a large number of closely spaced lines, the relative intensities of which do not change perceptibly with the strength of the magnetic field. On account of the insufficient dispersion, we have not yet been able to analyse these spectra in detail, but it is apparent that they are quite different from the absorption spectrum, and it seems that they behave in every respect as is to be expected for case (*b*).

The experiments are to be continued with higher dispersion, and a more detailed account will be given elsewhere.

Structure of the Raman Band of Water.

DURING some investigations, I have remarked that, with the increase of concentration of hydrochloric acid, the complex triplet structure of the Raman bands of water becomes more and more blurred. This result is in contradiction with a remark of Rao,[1] that the above-mentioned bands become sharper with the increase of the concentration of the electrolyte. In order to throw more light on that question I undertook some experiments, a detailed account of which will appear in the *Bull. de l'Acad. Polonaise*, now in the press.

A quartz bulb of the type described by Wood, which contained the liquid investigated, was covered, except for a narrow ring, with a black, opaque coating. It was put inside a low pressure mercury lamp in the form of a ring. The light scattered from the walls of the bulb could be eliminated by placing the bulb in a suitable position. The micro-photometer curves of the Raman spectrum, which I have obtained in this manner, show distinctly the triplet structure of the Raman bands of water, and the influence of the variation of concentration of hydrochloric and nitric acids on the distribution of intensities in the band.

The results obtained in the case of nitric acid are in accordance with Rao's observations, who simply described what could be seen on the plates with the naked eye. The water bands become sharper with the increase of the concentration, the central component splits in two parts, and the intensity of the short wave-length component increases rapidly. It seems strange that on Rao's micro-photometer records only the splitting of the central band could be seen, while the structure of the remaining bands was not visible.

A new band appears on the curve (*c.* 4675 A.), which corresponds to concentrated nitric acid. Gerlach had observed it already on his plates and has ascribed it to the HNO_2 molecules. However, on his micro-photometer curves that band could not be seen.

In the case of hydrochloric acid, this phenomenon has a different character. The intensity of both outer components decreases with the increase of the concentration, and the inner component apparently enlarges. Working with a solution of hydrochloric acid in water, I have remarked that the enlargement of the lines scattered by HCl, without change of the wave-length, has an asymmetrical character. The farther end of the enlarged line dissolves into a band, which ends abruptly on the long wave-length side by a sharp edge, the distance of which from the line is about 150 cm.$^{-1}$.

[1] Rao, *Proc. Roy. Soc.*, A, **130**, 489; 1931.

I HAVE photographed the Raman band of water excited by the mercury line 2536 at a temperature of 17° C. with a Hilger *E*1 spectrograph and exposures of about 125 hours. In the place of the two or three components which, according to the observations of other workers on the water bands corresponding to the same frequency difference and excited by the mercury lines 3650 or 4358, are found, I observed at least nine weak and diffuse components, which could not be reproduced but could be clearly seen with the naked eye under suitable conditions of illumination.

The accompanying reproduction (Fig. 1) is from one of the untouched photomicrographs taken with a large model of Moll's microphotometer, which has been modified in this Institute so as to lessen the irregularities of the registered curve caused by the largeness of the reduced grains of the plate in comparison with their scanty numerical density. The arrow indicates the mercury line 2759, which probably hides a tenth band. The other nine are clear.

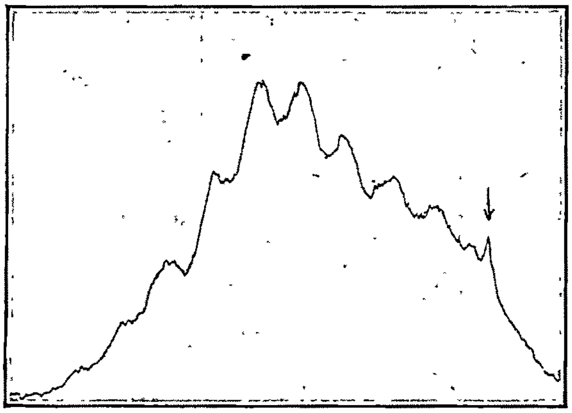

FIG 1.

The wave-lengths of each single component and the corresponding Raman frequency (average of the measurements carried out on photomicrographs of different plates) are given in the following table:

	λ.	$\nu_{\text{vac.}}$	$\Delta\nu$.
Exciting line . .	2536·5	39412·6	
1st component . .	2765	36155	3257·6
2nd ,, . .	2769	36104	3308·6
3rd ,, . .	2773	36052	3360·6
4th ,, . .	2777	35999	3413·6
5th ,, . .	2780·5	35954	3458·6
6th ,, . .	2784	35909	3503·6
7th ,, . .	2788	35857	3555·6
8th ,, . .	2792	35806	3606·6
9th ,, . .	2796	35755	3657·6

The average distance between two components is 50 cm.$^{-1}$.

The structural analogy between the present band and the band of water vapour at 2·7 μ examined by Neunhoeffer should be noted.[1]

A more detailed description will be published elsewhere shortly.

Photoelectrons and Negative Ions.

A SUMMARY of the results of an experimental research concerning the formation of negative ions from electrons may prove of interest. The electrons were generated by means of light emitted from a quartz mercury vapour lamp ('Home Sun' D.C. type) and incident upon a gold-plated electrode distant 2 cm. from a similar electrode. Between these two electrodes an alternating potential difference of 'square' wave form was established. During a fraction (f) of the time of a complete cycle the electric carriers advance to the receiving electrode; in the remainder of the cycle their motion is reversed, and they are withdrawn from the gas. The gas contained in the [illegible] vessel was air at various pressures; no purification of the air was attempted other than careful drying.

The experimental procedure consisted in determining for a given gas pressure (p) the curve representing the direct current (i_0) plotted against the applied potential difference (V), and also the curves which exhibited similarly the currents (i_1 and i_2) when the numbers of complete cycles per second were n_1 and n_2 respectively ($n_1 = 30$ and $n_2 = 600$ approx.). The ratios i_1/i_0 and i_2/i_0 were then plotted against $1/V$. The curves obtained were of the type given in the accompanying diagram (Fig. 1). In the curve B, which relates to the higher frequency, one observes a flat portion corresponding to the larger values of V and an apparent point of inflection. It was significant that this point of inflection always corresponded to the voltage which was known to be required in order that the negative ions might traverse the full distance between the electrodes.

In order to explain these curves, a mathematical expression for i/i_0 in its relation to V was developed, the assumption being made that the electric carriers are formed as electrons and that a fraction of these become attached to molecules during their passage through the gas, thus giving rise to negative ions. Mathematically, if N electrons traverse in the free state a distance x from the electrode where they originate, then, after traversing a further distance dx, the number of free electrons will be decreased by $\lambda N dx$, where λ depends on the nature of the gas and is, in addition, a function of V and p. It was found that the theoretical curves thus obtained exhi[illegible] the general characteristics of the experimenta[illegible] however, the values of λ which were require[illegible] the experimental curves into agreemen[illegible] theoretical relations were completely dif[illegible] two curves A and B. As it is not con[illegible] can depend on the frequency of co[illegible] conclusion is inevitable that the ass[illegible] above, which has been made the ba[illegible] experiments in recent years, is quite [illegible]

The mathematical expression for [illegible] modified, the assumption being made [illegible]

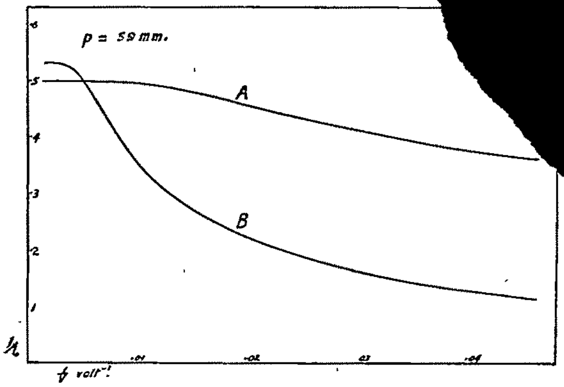

FIG. 1.

electric carriers formed at the electrode, a fraction θ consists of electrons and the remainder of negative ions. The assumption previously made was also retained, namely, that the electrons are liable to further attachment during their progress through the gas, the coefficent of attachment λ being defined as above. A close comparison between theory and experiment disclosed the result that the experimental curves could only be satisfied by values of λ extremely close to zero. On putting λ equal to zero the mathematical expressions for i/i_0 take the simple form:

$$i/i_0 = f - (1 - \theta)vx \qquad (x < f/v)$$
$$i/i_0 = \theta f \qquad (x > f/v)$$

where x is $1/V$, and v denotes nd^2/k, k being the mobility of the negative ion, and d the distance between the electrodes. The velocity of the electron is assumed to be large in comparison with that of the ion. The fraction of electrons (θ) is a function of the impressed voltage and of the gas pressure.

The agreement of experiment with the above theory was established over a range of pressures from 7 mm. to 1 atmosphere. The physical interpretation of the theory is that the great majority of negative ions are formed in the vicinity of the electrode at which the electrons originate; those electrons which do not give rise to negative ions near this electrode traverse in general the whole interval between the electrodes in the free state. Only an inconsiderable fraction of the ions, if any, can be formed by attachment in the body of the gas.

The values of θ in relation to the pressure and to the applied field have been obtained and will be given when the account of the experimental work is published in full.

University, Sydney, June 26.

Photosensitised Decomposition of Ozone by Bromine.

As a result of work on the photochemical chlorine-ozone reaction carried out at King's College, London,[1] experiments have been in progress on the bromine-ozone reaction in the hope of explaining the differences [illegible]tween the two reactions noted by Bonhoeffer[2] and [illegible]nted on by various authors since that time. It [illegible]d that chains of considerable length were [illegible] in certain circumstances, and to account [illegible] other facts, the formation of an oxide of [illegible] intermediate product was postulated. [illegible]ed that the formation of a similar un- [illegible]ll account for the high quantum effi- [illegible]omine-ozone reaction, and this receives [illegible]ork on the thermal process.[3, 4]

[illegible]umacher[3] concluded that it would be [illegible]pt the $Br_2 - O_3$ photo-reaction because [illegible] complicating factors, but preliminary [illegible] showed that the effect of the dark re- [illegible]l be minimised by working at atmospheric [illegible]th low concentrations of bromine and ozone [illegible]ge excess of oxygen. Working at 20° C., the [illegible]ion of any solid or liquid oxide is avoided, and [illegible]eaction appears to take place mainly in the gas [illegible]se. The natural dark reaction under these con- [illegible]tions is small for the first few hours, and can be partly eliminated by using balanced cells.[2] A few preliminary results may be of interest at this stage.

A high quantum efficiency is obtained of the same order as that found by Bonhoeffer, who bubbled his $O_2 - O_3$ mixture through liquid bromine before insolating with blue light.

As a general rule, there is no after-effect, indicating that little or no absorption of an intermediate compound on the walls is taking place in these experiments and this is also indicated by the fact that no appreciable change in transmission of $365\mu\mu$ or $546\mu\mu$ takes place on insolation. However, it is probable that this depends on the nature of the surface. The $Br_2 - O_3$ photochemical action differs from the $Cl_2 - O_3$ reaction in that there is no increase in rate of decomposition while the last few millimetres of ozone are being decomposed.[5, 1]

A further difference is that the quantum efficiency at $546\mu\mu$ is practically equal to that for $365\mu\mu$, although the wave-lengths correspond to absorption in the band and continuous regions respectively. (Compare Jost and Jung in the $H_2 - Br_2$ photo-reaction.)[6]

Experiments indicate a direct proportionality of rate to intensity in the region covered, and approximately the same quantum efficiency is obtained for mixtures containing 0·3 to 3·3 per cent bromine and 0·5 to 4 per cent ozone.

In view of the above, it is considered that an oxide of bromine is the 'carrier' in both the thermal and photo reactions. Lewis[4] indeed mentions this possibility, but inclines rather to the view that the carrier is an activated oxygen molecule, although the photo-decomposition of ozone scarcely supports this view.

Further experiments varying different factors are in progress with the view of elucidating both the thermal and photo-reactions.

Pottery with Flint Implements of Upper Palæolithic Facies from Swanscombe, Kent.

SOME time ago,[1] there appeared in NATURE a short account of a series of flint implements of Upper Palæolithic facies which I had found in a deposit, presumably of glacial origin, on Flamborough Head, Yorks. The cultural horizon of these implements was situated some six feet below ground-level and rested upon a layer of gravel which, in its turn, capped the Upper Purple Boulder Clay.

Some months later,[2] I announced my discovery of similar flint implements in the Brown Boulder Clay at Kirmington, Lincs, a deposit universally admitted as of glacial origin.

This year I located a similar series of flint implements, but associated with undecorated fragments of rough pottery, at Greenhithe, Kent. The site, which occupies a lateral valley, shows the following section:

G.	Surface soil with ground-level at 50 ft. above O.D.	2 ft.	0 in.
F.	Stony loam containing chalk fragments and an occasional 'raft' of Coombe rock	6 ft.	0 in.
E.	Brickearth with implements and pottery fragments	3 ft.	6 in.
D.	Sand with occupation-level at base .		6 in.
C.	Gravel	1 ft.	6 in.
B.	Coombe rock	5 ft.	0 in.
A.	Chalk		Plus.

Deposit E (the Brickearth) has been examined by Dr. R. H. Rastall, of Cambridge, who states that it is definitely not loess, but that it presents all the appearance of having been deposited by water action. The overlying stratum F (with its erratics, chalk fragments, and 'rafts' of Coombe rock) would seem to confirm the glacial origin of the implementiferous deposit of Flamborough Head previously described.

As a result of the generous assistance rendered by Mr. A. C. Davis, managing director of the Associated Portland Cement Manufacturers Co., Ltd., and the trustees of the Percy Sladen Memorial Fund, a series of excavations has been planned, reports on which will be published from time to time. The first excavation is well advanced, and a fine group of implements and pottery fragments has been recovered.

Research Items.

Bird Song and Weather.—Changes in weather, and especially sharp frost or snow, influence the amount of bird song, but the influence is different upon different species. H. G. Alexander has made careful observations of the effect of decided spells of hard weather upon birds in Birmingham (*British Birds*, Sept., p. 97). Frost reduces the amount of song, and effects especially the ground-feeding species, such as skylarks and thrushes, but cold winds have the same effect upon more arboreal feeders. Some species respond vocally to sunshine, like the coal-tit, and some are encouraged by rain, like the blackbird. It is suggested that sunshine or rain may affect favourably the food supply of these birds and thus may induce song, but rain stimulates blackbirds more than either thrushes or robins, although the food is very similar. There may be curious idiosyncrasies in the behaviour of closely related species. The song-thrush, the author says, sings in the early morning, and from late November onwards in favourable weather; the blackbird is rarely heard until February, and most of its early song is in the afternoon. Perhaps the 'song' means something different for the two species—more of a normal outlet for surplus energy for the song-thrush, more of a love song for the blackbird.

Nitrogen Content of Apples in Storage.—Pilling and Pearsall point out (Annual Report of the Agricultural and Horticultural Research Station, Long Ashton, 1930) that until now very little attention appears to have been paid to the changes in protein content in apples during storage. In view of the fact that such proteins, an essential protoplasmic constituent, form no less than 2 per cent of the dry matter of the apple, any considerable changes are likely to affect very seriously the continued life of the apples. Their preliminary observations, carried out in connexion with the fruit storage experiments at Long Ashton, seem to open a fruitful line of attack. During storage protein decomposition ensues, and the products—presumably after passing through amino nitrogen and ammonia nitrogen stages—accumulate as 'rest N' compounds of unknown origin and composition. An interesting result of this preliminary work is the fact that break-down in every case investigated seems to occur when the 'rest N' reaches a proportion of more than 17 milligrams per 100 grams of fresh weight.

Properties of the Earth's Crust.—The Geophysical Supplement to the *Monthly Notices* of the Royal Astronomical Society, vol. 2, No. 8, June 1931, contains four seismological papers, and one on forced tides in rotating rectangular basins of uniform depth (S. F. Grace). H. Jeffreys gives new determinations of the times of transmission of *P* and *S* waves at short epicentral distances, and E. Tillotson discusses the data for a 1923 earthquake originating in Yugoslavia, and finds that the travel times for *P* agree best with Jeffreys' tables; he also makes estimates of the thickness of the various layers near the surface, and of the energy of the earthquake (10^{21} ergs). R. Stoneley also discusses the thickness of the continental layers of Europe, from seismic data. H. Jeffreys in a theoretical paper examines the cause of the oscillatory movement in seismograms; in a homogeneous elastic solid an impulsive disturbance is not drawn out into a train of waves. The paper shows that the continuous variation of the earth's elastic properties with depth would not draw out the disturbance into an oscillation, nor can the mutual gravitation of the oscillating medium, nor friction and scattering, have this effect. The only suggestion that survives is that the oscillations are due to reflections of the original pulse within the surface layers, with partial reflection into the lower layers at each arrival at the interfaces.

The Guayra Falls of the Parana.—The Guayra Falls, a few miles above that town on the upper Parana river, have been known since the sixteenth century but have been seldom visited. In the September number of *Discovery*, Mr. E. C. Rashleigh gives an illustrated account of these falls, which, he claims, have the greatest flow of any falls in the world. There is a total drop of 373 feet in about thirty miles, and while no single fall exceeds 130 feet and no sheer leap is more than 65 feet, the volume and speed of the water make up for lack of height. Above the falls the river is 2½ miles wide, but the gorge below the falls is only eighty yards in width. The flow of water above the falls has been measured and averages 500,000 cubic feet per second, while in flood time it may be 1,000,000 cubic feet. This compares with 212,000 cubic feet at Niagara and 100,000 cubic feet at Paulo Affonso on the Rio São Francisco, which would appear to be the largest two of other falls. A Brazilian commission estimated the horse-power of the Guayra falls at 6,000,000, but Mr. Rashleigh points out that if it were possible to divert and canalise the whole river so as to utilise the total drop of 373 feet, the horse-power in flood season would amount to 174,000,000.

Ultra-Violet Window Glass.—Many of the glasses which have been produced capable of transmitting ultra-violet light of wave-lengths between 320 and 280 micro-millimetres, which are the most active therapeutically, deteriorate in their transmission on exposure for a few months to sunlight. The same effect is produced by exposure for a short time to a source, such as the quartz mercury lamp, richer in ultra-violet light. The August issue of the Bureau of Standards *Journal of Research*, Washington, contains a paper by Messrs. A. Q. Tool and R. Stair describing their experiments on the restoration of the transmitting power of such glasses by heating them in an electric furnace to definite temperatures for longer or shorter times extending to several days. They find that the colour of the glass disappears and the transmission is restored as the heating proceeds. At temperatures below 300° C., though the colour disappears, the transmission is only restored for the longer waves, and a temperature of 500° C. is necessary before it is restored for the shorter waves. The restoration is the more rapid the higher the temperature, but deformation of the glass begins about 600° C.

A New Electron-Inertia Effect.—In Maxwell's "Treatise on Electricity and Magnetism", he described three inertia effects which should exist in conductors, such as metals are now imagined to be. Two of these have been verified experimentally, in particular by Barnett and by Tolman, and in the *Philosophical Magazine* for August (p. 349) Prof. Barnett describes the observation of the third. It consists essentially in the angular acceleration of a coil of wire when the current through it is altered; the free conducting electrons are accelerated in one direction, and the coil itself accelerated in an opposite sense. The apparatus needed is naturally very sensitive, but was already set up in almost the requisite form for an investigation of the Einstein-de Haas effect of rotation by magnetisation. The minute twist imparted to the coil could be measured either by balancing it against another couple applied by the action of a second coil on permanent magnets attached rigidly to the main coil, or by the direct observation of the deflection, the former method proving the more accurate. The results show that the carriers of electricity have a negative charge—from the sense of the deflections—and that the ratio of charge to mass for the conducting particles is close to that found for electrons by other means, the best value obtained for the ratio being $1 \cdot 74 \times 10^7$ e.m.u., and the standard value $1 \cdot 77 \times 10^7$ e.m.u.

Accuracy obtainable with Gas-filled Photoelectric Cells.—In the *Scientific Proceedings* of the Royal Dublin Society for May, Dr. W. R. G. Atkins publishes a useful and interesting paper describing experiments on the accuracy obtainable with gas-filled photoelectric cells. The question arose in connexion with experiments made to determine by means of photometers the light penetration into sea water. Two cells, a gas-filled cæsium hydride cell and a gas-filled potassium hydride cell, were tested. The former was tested for constancy of emission after the glow discharge had been passed momentarily. It was found that when the anode potential was maintained at 143 volts, a variation of about 33 per cent occurred. Immediately after the glow discharge the sensitivity decreases about 2 per cent per minute, but after a time it begins to rise. The potassium cell was tested for constancy of emission in a similar way, and the variation was found to be within two per cent with a current of about five microamperes, the anode potential being 59 volts. At 166 volts the constancy appears to be somewhat less. The rate of decrease of sensitivity after the glow amounts to about 2 per cent at 166 volts and more than 3 per cent at 59 volts. It is therefore advisable to make measurements immediately after the discharge, which should be of momentary duration only. The potassium cell gives results which can be relied upon to within 2 per cent for post-glow readings for currents at least as great as five microamperes. The results refer to measurements made within a short period of time, and offer no evidence as to the constancy or inconstancy of the cell over long periods.

Astronomical Topics.

The Total Eclipse of the Moon on Sept. 26.—The second total lunar eclipse of the year is visible in England in circumstances closely similar to those of the eclipse of April 2. In each case the first contact of the shadow is about the time of moonrise, but as the moon is five degrees farther north on this occasion, the conditions at the end are slightly more favourable. Totality begins at $19^h\ 5^m$ U.T. ($8^h\ 5^m$ P.M. Summer Time), and lasts $1^h\ 25^m$. The moon leaves the umbra at $21^h\ 42^m$ U.T.; the shading of the penumbra remains fairly obvious for some minutes longer.

Total eclipses afford opportunity for observing the occultation of faint stars, which cannot be seen near the moon at other times. In fact, the best determinations of the moon's diameter are those derived from occultations during eclipses.

The study of the colours on the eclipsed moon is full of interest; they vary in different eclipses, and even in different parts of the disc. It is chiefly the lower layers of the terrestrial atmosphere that are effective in bending the sunlight that falls on the eclipsed moon; these layers vary greatly in transparency according to meteorological conditions. Hence, study of the moon reveals the integrated effect of the weather in the regions of earth that have the sun and moon on their horizon at the time. For most of totality the western part of this region will lie in the Atlantic Ocean.

Occasionally lunar eclipses are used for observing faint comets that cannot be seen in a moonlit sky; but it does not at present appear that this eclipse will be of use in this way.

It is of some interest to note that the small solar eclipse of Sept. 12, visible in Bering Straits, was the last eclipse of a series in the Saros cycle; one member of that series was the eclipse of May 3, 1715, when the sun was totally eclipsed at the Royal Observatory, Greenwich, for $3^m\ 12^s$. Flamsteed noted that the "weather was perfectly clear for the whole eclipse".

The Recent Opposition of Eros.—*Astr. Nach.*, No. 5815, contains notes by Prof. J. Hartmann and M. Dartayet on the observations of Eros made at La Plata early in the present year. The times of the exposures of the photographs were electrically recorded to one-tenth of a second. No screening of the planet was necessary, as its light did not differ much from that of the comparison stars. A series of photographs were taken at zenith distance 75°, to check the refrangibility of the planet's light; those for obtaining the parallax were at Z.D. 65° to 60°. 359 plates were taken near the meridian, which will be useful for deducing the mass of the moon. The planet and neighbouring stars were observed with the transit circle on eleven nights.

Plates for the investigation of the light-variation were taken on March 10, 21, and 25. The plates on the first night cover almost the whole of the light-period of 5¼ hours, in which there is a double maximum and minimum. The light range on the first two days was about three-tenths of a magnitude; on March 25 it did not exceed two-tenths. The times of maximum and minimum conformed well with the formula given by Rolf Müller in *Astr. Nach.*, No. 5768.

Perseid Meteors Observed in America.—The United States have a very active body of meteor observers, under the direction of Dr. Charles P. Olivier, director of the Flower Observatory, and author of a well-known text-book on meteoric astronomy. A bulletin from Science Service, Washington, D.C., dated Aug. 17, reports that the weather was unfavourable in the eastern States, but that successful observations were made at 47 stations in the United States and Canada. These are enough to prove that the maximum was quite a good one: "the rate after midnight rose to two per minute, which is well over the average. . . . Many brilliant meteors accompanied the shower."

As there is likely to be a good display of Leonid meteors about Nov. 17, it is desirable that as many observers as possible should co-operate. Those to whom such work is new should make themselves acquainted with the methods of observing them.

The Preservation of Food.*

THE Report of the Food Investigation Board for 1930 is notable, as in previous years, for the great variety of the researches which have been carried out under the Board's auspices. They are concerned with the changes taking place in meat and fish, fruit and vegetables on storage, especially at low temperatures, with the commercial application of the results obtained, and with the engineering problems involved in the construction and running of large stores. The report notes that the work of the Board has already been effective, in that two commercial gas stores for the storage of apples are now in operation: in one, over a period of five months, the losses during storage of 'Bramley's Seedling' apples did not exceed 0·5 per cent. Close touch is kept with investigators in other parts of the Empire: co-operation will be facilitated by the appointment of assessors, representing the Dominions and Colonies, to the Board during the past year.

The model store chamber at the Ditton laboratory, designed to hold 120 tons of fruit, is now in operation. The problem is to secure uniformity of temperature, humidity, and gas content, at desired values, inside a stack of material which generates heat, evaporates water, consumes oxygen, and evolves carbon dioxide. Large scale storage involves special questions, since the heat, water vapour, and gases produced in the body of the stack have finally to be removed from its surfaces: the greater the ratio of volume to surface, the greater is the difficulty of effective removal without the establishment of gradients. The investigations must therefore be carried out in special chambers arranged for the continuous scientific control of the environment and the measurement of the changes occurring in it: all measurements can be made from outside—for example, temperatures by a 200-point resistance-thermometer outfit.

Some of the scientific problems to be met by the biological engineers have also been investigated: one of the most important is the rate of evaporation from stored materials. Investigations have been carried out by A. J. M. Smith, during the year, on eggs and cheese. In the case of the former, there is no close correlation between rate of evaporation and area of surface, nor does the rate of air-movement (at constant humidity) have any effect on the rate of evaporation. In fact, evaporation appears to depend chiefly on the shell, which acts as the limiting factor: the rate falls off with time, but this is apparently not due to the eggs containing less water but to an increase in the resistance to diffusion of one of the membranes. During the first ten days or so of the life of the eggs the loss of weight is also due in part to output of carbon dioxide. The initial movement of water from the white is not only outwards but also inwards to the yolk, since the osmotic pressure of the latter is the higher: later the yolk loses not only the additional water but also some of that originally present. Examination of the water content of cheese at different levels from the surface showed that the gradient of water content was very steep, the bulk of the evaporated water coming from the outer 2 cm.

Investigations on the canning of fruit and vegetables have been carried out by T. N. Morris and J. M. Bryan. Using a tin-iron couple, it was found that oxygen increases slightly the corrosion of the tin by acid, but depresses that of the iron: in the absence of oxygen the corrosion of tin is negligible. The detinning of tinplate is most severe at low hydrogen ion concentrations (pH 4–5) within the range encountered in canned fruits: thus, corrosion is greater with cherries than with gooseberries. On the other hand, at low acidity, oxygen accelerates instead of depressing the corrosion of iron. It was also found that a rough surface accelerates both corrosion and the formation of hydrogen; that at high acidities exposed portions of the metal are attacked, at low, the pits and seams, and that traces of tin in solution inhibit the corrosion of iron. Traces of sulphur dioxide accelerate the corrosion of iron at high acidity, but retard it at low; gelatin and other inhibitors of acid corrosion may exert a powerful influence at high acidity but little or none at low. It may be necessary to store the fruit or vegetables before they are canned: strawberries and cherries can be stored frozen in sugar syrup; peas require blanching by boiling water before being frozen. On subsequent thawing and canning, the latter have the appearance and flavour of fresh canned peas, provided the liquid drained off on thawing is used as a covering in the tin: the thawed peas themselves resemble fresh peas if cooked at once.

During the year a survey of the freezing, storage, and transport of New Zealand lamb was carried out by E. Griffiths, J. R. Vickery, and N. E. Holmes: it was concerned chiefly with the measurement of the temperature, relative humidity, and movement of air surrounding the carcasses, as well as with the temperatures of the latter themselves, in the various stages of storage and transport. It was noticed that the 'bloom' or general appearance of the carcasses depended on breed, age, and nutrition of the sheep as well as on the treatment accorded after death. The value of beef is greater when it is imported chilled and not frozen, since it is ready for immediate sale, is well conditioned and tender, and little different in appearance from home-killed beef. The drawbacks of chilled, instead of frozen carriage, are microbial growth and rancidity. T. Moran, R. B. Haines, and C. H. Lea have shown that air movement delays the growth of moulds and the development of rancidity when meat is stored at 0° C.

Rancidity cannot be measured by chemical tests, as the products responsible for the taste and odour vary in different cases: it can be prevented by storage below $-10°$ C., when the meat is, of course, frozen: at $-5°$ C. the growth of moulds and yeasts is not completely inhibited. Light favours the development of rancidity, by hastening oxidation in the superficial layers of the fat: the process is autocatalytic and continues after subsequent removal to the dark. On the other hand, an unpleasant flavour develops in the dark, which is not due to atmospheric oxidation of the fat. It has also been found that an *Actinomyces* is responsible for the development of a musty odour in meat: it finds its way into the store with straw.

Work has also been carried out on the theoretical aspects of the subject of chilling and freezing: thus, muscle is irreversibly damaged when frozen below about $-2°$ C.: it can still form lactic acid, which can be removed by oxidation; but the resynthesis of the acid to glycogen can no longer take place. J. Brooks has shown that the discoloration of meat is due to the formation of methæmoglobin from hæmoglobin in the superficial layers: this process is inhibited by continuous storage at below $-10°$ C.

In the case of pig products, E. H. Callow has shown that carcasses of pork can be frozen, transported, and then made into bacon, provided that the fat is hard, otherwise rancidity develops: the nature of the fat depends on the diet of the pig. More lately it has been found that mild-cured or tank-cured bacon, frozen at − 35° C. and stored at − 10° C. or − 15° C., after slow thawing, and smoking in the case of the latter, tasted for the greater part like ordinary bacon after cooking, but in each case slight rancidity had developed in small areas of the fat. Work has also been carried out on the swelling of gelatin and pork muscle in solutions of sodium chloride.

---

* Department of Scientific and Industrial Research Report of Food Investigation Board for the year 1930. (London: H.M. tionery Office, 1931.) 3*s*. net.

The Torry Fish Research Station acquired the steam-drifter *City of Edinburgh* during the year. C. A. Reay has carried out further experiments on the freezing and cold storage of haddock. Under certain conditions an irreversible change in the muscle occurs which may not be very obvious on thawing but is evident after curing, since the glossy pellicle of the surface is absent and the tissue is friable, inelastic, and opaque instead of elastic and translucent. The rate of change is slowest at 29°–25° F. and − 9° to − 13° F., and quicker at the intermediate temperatures; at the higher, bacterial growth occurs, the lower involves greater expense in refrigeration.

Research work on fruit and vegetables has been continued. J. Barker has found that cyanide at first accelerates the respiration of the potato instead of inhibiting it as in the case of many animal tissues. The effect appears to be due to an activation of the starch-hydrolysing mechanism, so that more respirable material is available: later inactivation occurs. A. S. Horne has found that East Malling apples, which have a reputation for good keeping qualities, owe their freedom from wastage to absence of infection in the orchard: when infected they are less resistant than fruit from other areas. Resistance to fungal attack depends in part on the acid content of the apples, which decreases with age.

The Idu (Japan) Earthquake of Nov. 26, 1930.

SINCE the great disaster of 1923, Japan has been visited by three destructive earthquakes, in the Tazima province on May 23, 1925, when 428 lives were lost; in the adjoining Tango province on March 7, 1927, when 3017 persons were killed, and in the Idu peninsula on Nov. 26, 1930. Prof. A. Imamura has written two interesting papers on the last-named earthquake while a valuable memoir has recently been contributed by Mr. S. I. Kunitomi of the Central Meteorological Observatory.*

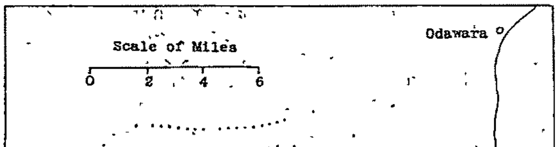

FIG. 1.

According to Mr. Kunitomi, the earthquake was felt over a land-area of 133,000 sq. miles, including the greater part of Japan. The series of Ito earthquakes, more than 4000 in number, closed at the end of May (NATURE, vol. 126, pp. 326, 971). Then followed a pause of about five months until Nov. 7, when a slight earthquake occurred with its epicentre near the Tanna basin. Every day after this, the fore-shocks of the Idu earthquake increased in number until, on Nov. 25, 734 shocks were recorded at the Misima Observatory near the north end of the peninsula. Up to 4 A.M. on Nov. 26, the total number of fore-shocks was 2165, of which 184 were felt at the observatory. Mr. Kunitomi's map representing the distribution of the fore-shock and after-shock epicentres shows that the former were as a rule clustered along the Tanna fault, while the latter were widely scattered over the epicentral region and especially at the bases of Mounts Huzi, Asitake, and Hakone, and off Cape Ooze.

One of the most useful sections of Mr. Kunitomi's paper is that which deals with the origin of the Ito and Idu earthquakes. He has studied the distribution of the directions of initial motion in the Idu earthquake and the stronger Ito earthquakes, especially that of March 22. In all of these earthquakes the distribution is the same, and implies in each a horizontal movement of the crust-blocks along a N.N.W. and S.S.E. line, or nearly along the course of the Tanna fault, the eastern block moving to the north and the western to the south.

The Idu peninsula lies on the west side of Sagami Bay, the bed of which and the surrounding shores formed the epicentral area of the Kwanto earthquake of Sept. 1, 1923. Prof. Imamura points out that there have been three epochs of seismic activity in this region, in 818, 1703 and 1923, and that the first and third were followed, after 23 and 7 years respectively, by destructive earthquakes in the Idu peninsula. The recent Idu earthquake may thus, he suggests, be regarded as an after-shock of the earthquake of 1923.

The earthquake occurred on Nov. 26, at 4 h. 3 m. A.M. (Nov. 25, 7 h. 3 m. P.M., G.M.T.). In a sketch-map, the essential features of which are here reproduced (Fig. 1), the broken lines represent the faults along which dislocations occurred during the earthquake, the outer dotted line bounds the area in which at least 1 per cent of the houses collapsed, the inner dotted lines I-IV, the areas in which the percentage was not less than 25. It was in the areas II-IV that the greatest losses of life and property occurred, 259 persons being killed and 2142 houses destroyed.

Of the faults that appeared during the earthquak four are especially noteworthy. (i) The Tanna fa

* *Tokyo Imp. Acad. Proc.*, vol. 6, pp. 419-422; 1930, and *Japan. Jour. Astr. Geoph.*, vol. 8, pp. 51-65; 1931. *Tokyo Geoph. Mag.*, vol 4, pp 73-102; 1931.

crosses the Tanna tunnel at right angles, about 500 feet below the surface. In the tunnel itself, the crust on the west side was shifted 7 ft. 10 in. to the south and 2 ft. 0 in. downwards relatively to that on the east side; though, at the surface, the dislocation was much less marked. (ii) The northern or Hakone fault, trending north-west, may be a segment of the Tanna fault. (iii) The Oona fault begins near Ukihasi and runs S. 30° W., with a relative southward shift of the west side amounting in one place to 3 ft. 3 in. (iv) The southern segment of the latter fault, or Kadono fault, trending S. 70° W., with relative shift of the west side of 4 ft. 3 in. to the south and 1 ft. 8 in. upwards.

From a study of the seismograms obtained at Tokyo, Prof. Imamura distinguishes four series of waves coming from as many different origins, that are probably represented by the areas I-IV in the accompanying map. The movement of the whole block-system started north of Ukihasi (in lat. 35° 2′ N., long. 139° 0′ E.), passed northwards with comparative quietness along the Tanna fault, and southwards, with sharp destructive shocks caused by the displacements of the three blocks II, III, and IV. The crust on the west side of the fault-system was shifted relatively southwards, the whole movement coming to an end after the lapse of about 10 seconds. The stress causing this block-movement probably acted in the same way as that in the great Kwanto earthquake of 1923; in other words, the recent Idu earthquake was an after-shock of the Kwanto earthquake.

C. DAVISON.

The National Radio Exhibition.

THE National Radio Exhibition, which was opened at Olympia on Sept. 18, occupies a floor space three times as large as last year and is now the largest radio exhibition in the world. The exhibition is organised by the British Radio Manufacturers' Association, and is arranged in such a well-planned manner that it cannot fail to be of interest to all broadcast listeners, whether technically minded or not. This exhibition definitely supports the idea which was becoming evident last year, that the radio manufacturing industry has passed through its somewhat uncertain experimental stage to that of steady development along trustworthy and well-established lines. The modern commercial radio receiver compared with its prototype of a year or two ago, which resembled an ill-assorted collection of components wired together in a box, is built somewhat on the lines of a car chassis.

Apart from the progress made in the design of receivers based on well-established principles, two recent developments are indicated in the exhibition. The first is an attempt to improve the selectivity obtainable in reception without any appreciable sacrifice of the quality of reproduction. More than one method of reaching this objective is being investigated, and it is possible that the results obtained may to some extent alleviate the interference difficulties which sometimes arise when transmitting stations are in too close proximity to one another, both in a geographical sense and from the point of view of their operating frequencies. The second and perhaps more recent novelty in Great Britain is the introduction of the 'variable-mu' valve, that is, of a valve in which the action of the grid in controlling the anode current varies along the axis of the electrode system, usually as a result of a variation in pitch of the turns of the grid. Such a valve, having a variable amplification factor according to the actual conditions under which it is operating, provides a means of avoiding certain distortion effects encountered in the normal type of screen-grid valve. A means of overcoming the effects of variation of the incoming signal due to fading and other causes is also provided by the new valve, which may be operated under conditions securing automatic volume control in the radio-frequency portion of the set.

A prominent exhibit is that of the British Broadcasting Corporation, which includes a large map of the British Isles showing the density of population in relation to the broadcasting stations. A study of the map reveals that the B.B.C. stations are placed in the most advantageous positions to secure that the great majority of the population are within the service area of one or more stations. Apparatus is also installed on the B.B.C. stand to supply programmes to all loud-speakers operating in the exhibition.

For the rest, the exhibition shows the great range of modern receiving sets which are now available to suit all tastes and length of purse. The great modern tendency is to make the receiver a self-contained unit, including the loud-speaker, and ready for connexion to the electric supply mains. The larger and more expensive models contain also an electrically operated gramophone, and in some cases these now embody automatic record-changing mechanism by means of which half an hour's continuous gramophone music can be obtained without any attention. The more successful of the portable receivers remain in a somewhat improved form, while battery-operated models are still produced for those to whom an electric supply is not available. Altogether it may be said that the receivers show a marked improvement in design and performance over those exhibited last year, while the selling prices are in most cases appreciably lower.

Birthdays and Research Centres.

Sept. 28, 1873.—Prof. J. L. COOLIDGE, professor of mathematics in Harvard University.

I am at present engaged on a history of geometrical methods. This is a long work that will cover many years.

A problem to which attention might usefully be given is the situation of the singular points of a rational plane algebraic curve.

Sept. 28, 1889.—Prof. H. MUNRO FOX, professor of zoology in the University of Birmingham.

Protoplasm contains a considerable number of elements, some of them present only in traces. Of these, some may be of considerable functional importance. During the last two years, in collaboration with Mr. H. Ramage, I have been making a quantitative spectrographic study of the presence of traces of elements in the tissues of a wide variety of animals.

Some years ago I carried out a physico-chemical investigation of chlorocruorin, a green blood pigment present in certain polychæte worms. Chlorocruorin turned out to be the only known substance having a chemical structure closely similar to hæmoglobin. By its resemblances and differences it throws light on the nature of hæmoglobin. At the same time chlorocruorin has a number of peculiarities. I am at present studying the blood circulation, metabolism, and mode of life of the animals possessing chlorocruorin, with the view of elucidating the functional rôle of this respiratory pigment.

Oct. 2, 1875.—Prof. A. W. CONWAY, F.R.S., professor of mathematical physics, University College, Dublin.

In conjunction with Prof. M'Connell, of Trinity College, Dublin, vol. 2 of Hamilton's "Mathematical

Works" is being prepared. This entails the examination of the immense amount of unpublished MSS. which Hamilton left behind. Hamilton left unpublished many dynamical ideas which are attributed to later writers.

As time permits, I am investigating the connexion between wave mechanics and relativity.

Oct. 2, 1876.—THOMAS SHEPPARD, director of the Hull Municipal Museums, and editor of the *Naturalist.*

Realising the importance of the work of my old friend Dr. C. Davies Sherborn, I began early the thankless task of compiling bibliographies relating to British geology, prehistoric archæology, zoology, and botany. These have been published by the Yorkshire Geological Society, British Association, East Riding Antiquarian Society, and in the *Naturalist.* The north of England bibliographies formerly compiled by Dr. A. Harker have been prepared by me since 1893, and in 1915 was published the bibliography of Yorkshire geology, 1534–1914 (666 pages).

In editing the natural history, geological, antiquarian, and museum publications during the past forty years, I have endeavoured to popularise various aspects of science. Towards this end I have written papers and books on numerous subjects, and am gratified by being told that there are more entries under my name in the Geological Society's card catalogue than under that of any other British geologist, living or dead.

Always interested in forgeries, I have caused trouble in high places by exposing fakes.

More than thirty years ago I was appointed to take over the Museum of the old Hull Literary and Philosophical Society, then typical of its kind, and this educational work has been so much appreciated by my fellow-citizens that we now have separate museums specialising in prehistoric archæology, natural history, commerce and transport, fisheries and shipping, applied art (ancient and modern), a memorial to William Wilberforce, and folk-lore. Three others are in preparation.

Societies and Academies.

LONDON.

Institute of Metals, Sept. 15 (Annual Autumn Meeting, Zurich).—**A. J. Murphy**: The constitution of the alloys of silver and mercury; with an appendix by **G. D. Preston** on the X-ray examination of the system silver-mercury. Progressive additions of mercury to silver cause a continual reduction in the temperature of the initial freezing point down to − 38·8° C., the freezing point of mercury. No alloy in the series has a freezing point lower than that of pure mercury. Silver can retain in solid solution 55 per cent by weight of mercury at 276° C., the amount probably increasing somewhat at lower temperatures.—**A. von Zeerleder**: Influence of variations in heat-treatment and ageing on duralumin. Quenching in hot water or in oil causes less deformation, and if the temperature of the quenching medium, as well as the ageing temperature, be 50° C., there is no disadvantageous influence on the physical properties. Measurements of the electrochemical potential, electrical conductivity, tensile and corrosion properties showed that a temperature of 145° C. (293° F.) had a decidedly disadvantageous influence.—**W. E. Alkins** and **W. Cartwright**: Experiments in wire-drawing. (1) Behaviour of a composite rod. Composite round rods of annealed copper, built up by drawing a number of tubular layers of equal thickness over a central solid core, have been drawn in drafts of varying severity through straight-sided dies of three different angles of taper. Butt ends when drawn through the dies become concave without showing any steps between the layers; the concavity increases with the angle of taper of the die and also with the amount of reduction at the draft. All the layers undergo a proportionate reduction in thickness and therefore the same relative reduction in area of cross-section.—**E. L. Francis** and **F. C. Thompson**: The drawing of non-ferrous wires. The power required to draw wire is directly proportional to the maximum stress of the original material. With tungsten carbide dies, the pull required is practically independent of the speed of drawing over a wide range. A comparison is made between the efficiency of steel, carbide, and diamond dies.—**H. W. Brownsdon** and **E. H. S. van Someren**: Application of the spectrograph to the analysis of non-ferrous metals and alloys. The possibilities and limitations of spectrographic methods are reviewed. Methods for the routine spectrographic examination of brass and some lead alloys are outlined, and tables are given indicating the relationship between impurity or minor constituent concentration and relative line intensities.—**D. M. Smith**: The spectrographic assay of some alloys of lead. The method is based on standards of known composition either synthetically prepared or determined by accurate chemical analysis. One of its great practical advantages is that it is very much more rapid than ordinary chemical assay of these metals. Spark spectra are preferred, as giving more consistent results than arc spectra. By simple direct comparison of spectra the constituents can be determined within the range 0·1-1 per cent, with an accuracy of 10 per cent.—**John L. Haughton** and **Ronald J. M. Payne**: Transformations in the gold-copper alloys, with an appendix on X-ray examination of gold-copper alloys, by **G. D. Preston**. By recording autographically the variation of resistance with changing temperature of alloys of composition ranging between 20 per cent and 70 per cent atomic of gold, and by measurements of the specific resistance of alloys slowly cooled to room temperature, the transformations in alloys with compositions in the neighbourhood of those corresponding with the compounds AuCu and $AuCu_3$ have been confirmed, and the presence of another transformation in alloys approximating to the concentration of compound Au_2Cu_3 has been established.—**N. S. Kurnakow** and **N. W. Ageew**: Physico-chemical study of the gold-copper solid solutions. Both annealed and quenched alloys were studied. The existence of the compounds AuCu and $AuCu_3$ has been confirmed by constructing isothermal diagrams of the electrical resistance, and the limits of the solid solutions have been indicated.—**M. Cook** and **E. C. Larke**: Physical testing of copper and copper-rich alloys in the form of thin strip. Consistent results for tensile strength and elongation are obtainable on all the materials down to and including 0·02 in. thickness. One of the most satisfying methods of measuring hardness is the diamond pyramid static indentation method. Cupping machines, although they may measure some kind of ductility and, if properly correlated, may afford a good sound indication of the behaviour of a material for cupping and drawing operations, are limited in respect of specification.

(*To be continued.*)

PARIS.

Academy of Sciences, August 3.—**A. Lacroix**: The tectites of the Philippines. These correspond closely in appearance and chemical composition with the tectites from Indo-China, Malay, and Borneo, and have probably the same origin as the latter.—**Aimé Cotton**: Polarising prisms with normal field based on internal crystalline reflection.—**Charles Achard, Augustin Boutaric, and Maurice Doladilhe**: The physical properties of the blood serum and of the proteins separated from this serum by the acetone method in man and in some animals in the normal state. The experiments detailed show that colloidal suspensions made up from the proteins separated from a serum and a volume of water equal to the original volume of a serum possess a viscosity and an optical density practically identical with those given by the original serum. Hence the properties of the proteins separated by the acetone method appear to remain unaltered.—**Gabriel Bertrand and P. de Berredo Carneiro**: The active principle of guarana. The presence of a new alkaloid in guarana (Schar, Thoms, Nierenstein), not caffeine, is definitely negatived by the author's work. He found 4·8 per cent of caffeine, and careful examination of this failed to show the presence of any other alkaloid.—**André Blondel**: Some new forms of the method of recording and observing the angular deviations of internal combustion engines. A neon lamp is substituted for the spark or arc lamp used in earlier methods.—**A. Bigot and J. Dubois**: The presence of the Ordovician in the Moroccan Anti-Atlas. This is proved by the discovery of an *Acidaspis Buchi* in an exceptional state of preservation near the base of the schists and quartzites of Djebel Tachilla.—**G. Pfeiffer**: The reciprocal relation between two systems of linear equations in involution.—**Jean Placinteanu**: The true vibration of ionised gases.—**J. Cabannes and E. Canals**: The Raman effect in a crystal of sodium nitrate.—**René Audubert and Jean Roulleau**: The rôle of the phenomena of photoconductance in the photovoltaic effect. The results of experiments described show that the phenomenon of photoconductance cannot be considered as the essential factor of the photoelectric effects: if it intervenes, it should be considered as a secondary phenomenon.—**G. Darzens and André Lévy**: The direct bromination of metacresol. The exact conditions for the direct bromination of metacresol to monobromocresol are given: the compound was proved to contain the bromine atom in the para position to the hydroxy group.—**P. Vayssière**: Some observations on the migratory acridians.—**Louis Bounoure**: The Golgian nature of a characteristic cytoplasmic element of the germ in the first stages of the development of the frog.—**A. Paillot**: Parasitism and symbiosis in the aphides.—**E. Landauer**: Study of a medium for cultivating the spirochæte of fowls.—**G. Delamare and C. Gatti**: Some characters of *T. rigidum*.

WASHINGTON, D.C.

National Academy of Sciences (*Proc.*, Vol. 17, No. 6, June 15).—**E. M. East**: Immunity to sugar cane mosaic acquired by the host. Sugar cane infected with mosaic can throw off all pathological symptoms and remain apparently healthy for a time. It is not known whether reappearance of mosaic is due to re-infection or whether the mosaic virus is merely reduced in virulence. Strains subject to mosaic, though apparently healthy, give the same precipitin test as those definitely infected with mosaic, whereas strains never known to have mosaic react differently.—**D. C. Cooper and R. A. Brink**: Cytological evidence for segmental interchange between non-homologous chromosomes in maize.—**Andrew Watson Sellards**: The behaviour of the virus of yellow fever in monkeys and mice. Yellow fever virus maintained by passage from brain to brain of mice loses its virulence for monkeys by ordinary routes of injection. Intraperitoneal injection of such virus immunises monkeys against typical yellow fever virus; similar inoculation of man may sometimes be justifiable.—**Frederick D. Rossini**: The heat of combustion of methyl alcohol. A stream of air was saturated with the vapour and burnt at constant pressure in an oxygen atmosphere. An electrical method was used to determine the thermal effect (NATURE, 127, 506, March 28, 1931). The heat of reaction found was 173·63 ± 0·05 kgm.-cal. per mole at 15°.—**Eric G. Ball and W. Mansfield Clark**: A potentiometric study of epinephrine.—**William Hovgaard**: The distribution of stresses in welded and riveted connexions. Theoretical investigations suggest that when a girder of limited length is attached to a major structure subject to tension or compression parallel to the girder, there is marked concentration of shearing stresses at the ends of the girder, and their intensity is much greater than ordinarily supposed. Experimental evidence of the effect is given. This has important consequences in ship design and may account for fracture of deck plating at corners of deckhouses, hatches, etc.—**Harry Grundfest**: The relative effectiveness of spectral radiation for the vision of the sun-fish, *Lepomis*. The fish is placed in a cylindrical glass tank surrounded by a cylindrical screen of equal and alternate vertical bars and spaces. The tank is placed on a glass-topped table and illuminated from below. Light is reflected through the screen round the tank from the inside of a hollow truncate 45° cone. Rotation of the screen causes movement of the fish, which is usually motionless. The least amount of illumination (spectral energy) causing movement is determined for various regions of the spectrum; the wave-length of maximum efficiency is 535–545mμ, corresponding well with the maximum of the visual purple absorption (540mμ). This indicates that visual purple is the photosensitive agent for dim vision. Substituting a fine wire mesh for the screen, measurements were made at bright illuminations. The maximum efficiency is then at 640mμ. This suggests that in fishes, as in man, there are two visual mechanisms, for dim and bright illuminations respectively.—**J. F. Ritt**: Systems of algebraic differential equations.—**Gordon Pall**: The number of representations function for positive binary quadratic forms.—**Edward Kasner**: Dynamical trajectories and the ∞^3 plane sections of a surface.—**Einar Hille and J. D. Tamarkin**: On the summability of Fourier series (4).—**W. T. MacCreadie**: On the stability of the motion of a viscous fluid.—**A. Adrian Albert**: Normal division algebras of order 2^{2m}.—**Edwin H. Hall**: Electric conductivity and optical absorption in metals, once more. A discussion of the results obtained by Meier and by Hagen and Rubens on the basis of the dual theory of conduction.—**W. W. Coblentz, R. Stair, and J. M. Hogue**: The spectral erythemic reaction of the human skin to ultra-violet radiation. Isolated spectral lines from a large quartz monochromator were used, and the time of exposure to produce a minimum perceptible erythema on the authors was determined. The wave-length range of the erythemogenic rays begins about 315mμ; the response wave rises abruptly to a maximum at 297mμ, descends less abruptly to a minimum at about 280mμ, and rises to a less intense maximum at about 250mμ. The erythema produced by the shorter wave-lengths is very transitory. The response curve is practically the same for different persons.

Official Publications Received.

BRITISH.

Transactions of the Royal Society of Edinburgh. Vol. 57, Part 1, No. 2: A Contribution to the Molluscan Flora of the Laki and Basal Khirthar Groups of the Indian Eocene. By L. R. Cox. Pp. 25-92+4 plates (Edinburgh: Robert Grant and Son; London: Williams and Norgate, Ltd.) 10*s*

Racial Prejudice.

PROF. FRANZ BOAS showed his usual courage in taking "Race and Progress" as the subject of his presidential address to the American Association for the Advancement of Science, at Pasadena on June 15 last. He essayed once more to raise the complex question of the intermingling of racial types from the slough of political controversy into which it has fallen in the United States and to discuss it dispassionately in the 'dry light' of scientific evidence.

Unfortunately, in this matter, science, or perhaps it would be more correct to say those who seek to interpret scientific data and apply their interpretations to practical affairs, speak with no united voice. Prof. Boas, looking on Europe with a cosmopolitan eye, views it as a whole, a congeries of peoples, each of no single fixed and determinate type, or able to lay claim to be regarded as a pure race—racial types, in fact, being largely ideal. Thus, he pointed out, it would be "a rash undertaking to determine the locality in which a person is born solely from the bodily characteristics". In the populations of the various parts of Europe many individuals might as well belong to one part of the continent as another. Yet, he goes on to argue, while it is not necessary to consider the great difference in type that occurs in a population as due to mixture of different types, it is easy to see that intermingling has played an important part in the history of modern populations. Further, there is no evidence that mating between individuals of different descent or different type results in progeny less vigorous than that of their ancestors. After dealing with the effects of heredity, environment, and selection upon bodily form, Prof. Boas surveyed the data of physiology and psychology from the racial aspects, and arrived at the final conclusion that the biological difference between races is small and that it is the social setting with which we have to reckon. Race antagonism is thus resolved into a matter of social group consciousness.

In this conclusion, Prof. Boas inevitably challenges comparison with the view taken by Sir Arthur Keith in his recent rectorial address in the University of Aberdeen. Sir Arthur, naturally preoccupied with the political and economic situation as it is in Europe to-day, and looking upon it as a phase in a long course of an evolutionary process, gives the fullest weight to the survival value of the concept of race. While he would agree with Prof. Boas that 'racial type' in its complete implication is an ideal rather than an observed fact, he views ‘ racial prejudice ’ as a potent factor of progress in human affairs. Prof. Boas does not ignore the opposition in their respective views. Not only does he explicitly disagree with Sir Arthur in his view of the beneficial effect of war, but he also traverses his dictum that “ race antipathy and race prejudice Nature has implanted in you for her own end—the improvement of mankind through racial differentiation ”. Of this Prof. Boas says, “ I challenge him to prove that racial antipathy is ‘ implanted by Nature ’ and not the effect of social causes which are active in every closed group ”.

In reality, Prof. Boas is by no means so far removed from Sir Arthur Keith’s position as he would have us believe. In the practical problem Prof. Boas has specially in view, racial and social group tend to coincide. In Europe the lines of demarcation are geographical. In the United States the conflict is internal ; the races are not segregated within national boundaries as they are, broadly speaking, in Europe. Sir Arthur Keith has expressed the view that every nation is a potential race. Hence the conflict that presents itself to Prof. Boas as calling for the consideration of anthropological science is both simpler and yet in some ways more difficult of solution than it is in Europe. He points out that the difference between racial groups is an important element in establishing racial grouping and in creating conflicts—there are no ethnic groups in Europe so widely diverse as negro and white ; but the actual relation is identical whether the grouping be racial, national, or denominational. The group is idealised and there is an emotional desire for its perpetuation. This leads to group endogamy in the desire to keep the race or group pure.

Here it will be seen that Prof. Boas is virtually in agreement with Sir Arthur Keith, in so far as the latter would not exclude social factors from the influences which mould the potential race. This would seem to be the line upon which the negro problem is at present developing in the United States. However, regarding the situation as it stands, Prof. Boas’ conclusion is that while society is stratified in social groups which are racial in character, there will be racial discrimination ; but that wherever members of different races form a single social group with strong bonds, racial prejudice and racial antagonism will lose their importance and eventually disappear. Applying the terms of a general conclusion to a particular instance, Prof. Boas’ address virtually sets out the argument for the case that so long as the United States insists upon a social stratification in racial layers, the penalty must be paid in the form of a racial struggle.

In effect, then, Prof. Boas interprets the evidence of anthropological science as favouring the ‘ melting pot ’ view of population problems—that is, racial fusion, as against the conception of a dominant superior racial type, the theory which at present holds the political field. Although he might not admit it, on his view the United States might well qualify to be regarded as at a stage in Sir Arthur Keith’s evolutionary process on its way to becoming a ‘ potential race ’.

Symbiosis.

Tier und Pflanze in Symbiose. Von Paul Buchner. Zweite vollig umgearbeitete und erweiterte Auflage von “ Tier und Pflanze in intrazellularer Symbiose ”. Pp. xx + 900. (Berlin : Gebrüder Borntraeger, 1930.) 96 gold marks.

THE growth of knowledge in this subject since the first edition of this work in 1921 is reflected in the present edition of 900 pages as compared with its predecessor’s 462 pages. In an introduction of 18 pages the main branches of the subject are briefly surveyed. The oldest of these dates from the fifties of last century, when attention was directed by several observers to the presence of chlorophyll in infusoria, *Hydra*, Turbellaria, and the fresh-water sponge (*Spongilla*) ; but the green colour was regarded by some authorities as due to a special kind of ‘ animal chlorophyll ’ or to the minute plants taken into the respective animals from without and living as parasites or serving as food. When Hamann (1882) showed that the green bodies in the egg of *Chlorohydra* do not arise there but wander in from the parent, he established the transmission of symbionts, and further work demonstrated that the green bodies are complete cells. Other investigations showed that the yellow cells in the Radiolaria issue after the death of the animal and a flagellate stage ensues.

In a section of about 180 pages the author considers the cases in which symbiotic Algæ are concerned, beginning with the Protozoa and working systematically through the phyla up to the Tunicata. For each group of animals the history of our knowledge of the symbiosis is briefly surveyed, and the position occupied by the symbiont, the mode and course of infection of the animal and the resultant effects are described. In his comment on the published observations upon the relations between Algæ and corals, the author states

CALCUTTA UNIVERSITY LIBRARY

Book No........

his belief that the amount of animal food taken by corals has been generally underestimated, and this is substantiated by the recent observations of Dr. C. M. Yonge on the feeding of corals on the Great Barrier Reef. A particularly interesting part of the volume is that on the artificial suppression and on the artificial establishment of symbiosis of Algæ with Protozoa, *Hydra*, and *Convoluta*, with a discussion of the factors necessary for these partnerships.

The first observations on the symbiotic relations of fungi with animals were those upon the culture, by ants and by termites, of fungi as food. Modern work on intracellular symbionts of fungal nature dates from 1910, when Pierantoni and Šulc independently explained the true significance of the so-called pseudovitellus of Homoptera—up to that time regarded as a food reserve, but then shown to be a complicated structure, termed the mycetome, harbouring the symbionts. All Homoptera that have been investigated have been found to live in more or less complex symbiosis. Some have two, three, or even four different sorts of symbionts. Following the discovery of symbionts in insects which feed on plant juices came that of symbionts in blood-sucking animals—tsetse flies, lice, ticks, mites, leeches, and more recently in bed bugs and the Pupipara—which the author suggests may prove to be of medical interest as some of the symbionts perhaps belong to the Rickettsias.

The author gives a number of interesting recent observations on insects which feed on wood or on a diet rich in cellulose, and carry yeasts, bacteria, and other organisms, the systematic position of which remains uncertain; for example, in the mature female of the cerambycid beetles tubular intersegmental glands associated with the vagina are organs filled with the symbionts, clusters of which are expelled as the eggs are being laid and can be demonstrated on the outer surface of the eggs.

In a chapter of 90 pages are brought together the observations on bacterial symbionts concerned in the production of light in animals, especially by the luminous organs of *Pyrosoma*, of fishes and of cephalopods, and by the 'accessory nidamental glands' of certain cephalopods.

The author traces the steps in the modes of transmission of symbionts, beginning with insects in which the organisms are present in the rectum, from which they are readily passed out as eggs are laid. In other cases anal folds or sacs, or vaginal and intersegmental sacs filled with bacteria, are responsible for infection of the eggs, while in *Glossina* and the Pupipara the symbionts are transmitted to the larva by the uterine 'milk glands'.

In discussing the part played by symbionts in development, the author points out that in many cases the presence of these organisms causes little or no modification; but in the viviparous aphids the abundant flow of symbionts into the developing embryo brings about far-reaching modifications.

While the work of Cleveland and others has elucidated the part played by the Protozoa in the intestine of termites, there appears to be no definite conclusion as to whether the numerous ciliates in the stomach of ruminants—in 1 c.c. of the contents of the rumen of the sheep nearly a million ciliates were found—or in the cæcum of the horse are helpful to the host.

The volume concludes with a list of works on the subject occupying 47 pages, an index of authors referred to, and an index of the genera of animals and plants considered in the text.

Dr. Buchner, who is to be warmly congratulated on his thorough treatment of the subject, has produced a volume of great interest. With justifiable pride he states that what he describes he has in large part seen himself, and that considerable portions of the subject have been investigated either by him or with the help of his pupils, to a score of whom he expresses his thanks. The 336 illustrations are beautifully reproduced and many of them are original. A statement of the magnification and, in a number of cases, additional lettering of the parts, would have made the drawings of still greater value.

Plants and Geology.

Plant Life through the Ages: a Geological and Botanical Retrospect. By Prof. A. C. Seward. Pp. xxi + 601. (Cambridge: At the University Press, 1931.) 30*s*. net.

IN this book, Prof. Seward fulfils his promise to supplement his four volumes on fossil plants by a general review of the floras of the past, more intelligible to the general reader than the text-book. The result is an admirable treatise, which perhaps no one but Prof. Seward could have written, bringing the records of fossil plants into constant relation with the geological changes in their environment. As he says: "It is one thing to study the fossils by themselves; it is another and a more attractive thing to think of them as living plants in a real world".

The book is abundantly illustrated by pictures, maps, and tables of distribution. A striking and novel feature is introduced in the ten reconstructions of ancient landscapes, drawn for the author by a skilled artist, Mr. Edward Vulliamy. These views, at once accurate and picturesque, are probably the best restorations of past floras hitherto attempted. As in some of the author's earlier writings, every chapter is preceded by an appropriate motto, sometimes rather cynical, as in that of the chapter on classification of plants, "We do but learn to-day what our better advanced judgments will unteach to-morrow" (Sir Thomas Browne); sometimes poetic, as in the quotation from Isaiah, introducing the barren Triassic period: "And the desert shall rejoice, and blossom as the rose".

The first four chapters are purely geological, setting the stage, as it were, for the mysterious drama of plant evolution. The discussion of Wegener's famous hypothesis of shifting continents shows that no decision is possible, though the palæobotanist may be inclined to favour a supposition which would help him out of some of his difficulties.

Referring to the petrified remains with structure preserved, the author says: "We see in the architecture of stem and leaf the same accuracy of correlation between structure and function as in plants of the present day" (p. 48)—an important and true conclusion, which has not always been recognised.

In considering the Cambrian, Ordovician, and Silurian records, the author points out that the almost exclusively marine strata of these periods lead us to exaggerate the suddenness of the creation of a land-flora when we reach the continental Devonian sediments. "Land-plants may well have existed long before, but their remains had no fair chance of preservation" (p. 101). Speaking of the early Devonian land-flora he says: "The probability is that some of the older Devonian plants are examples of transformed Algæ; others . . . are more likely to be descendants of simpler ancestors which had long been accustomed to live above the sea" (p. 112). In connexion with this subject, one of the very rare slips in description must be mentioned. In describing Lang's very early *Dadoxylon Hendriksi*, from Cornwall, it is stated that the secondary tracheids are pitted on all the walls, not, as in recent Gymnosperms, on the radial walls only. This is true of *Palæopitys Milleri* but not of the Cornish plant, which Lang has shown to be a true *Dadoxylon*, with the typical Araucarian structure.

Going on to the much richer and more advanced Upper Devonian flora, we are at once confronted with difficulties of distribution. The existence of a luxuriant vegetation so far north as lat. 77° N. is one of the many unsolved problems of geological history.

The earlier Carboniferous vegetation was comparatively uniform all over the world, as shown by the occurrence of practically identical forms of *Lepidodendron* in Australia, Spitsbergen, Europe, and North America. The subject of the abundant later Carboniferous vegetation is introduced by the excellent reconstruction of a Coal Age landscape. The author warns us against supposing that the giant Calamites and Lepidodendra of the Coal-forests were the ancestors of our modest horsetails and clubmosses. The latter groups probably owe their origin to such extinct forms as *Equisetites* and *Selaginellites*, which were always comparatively small plants.

Attention is directed to the important work of Prof. Halle on the Permo-Carboniferous flora of northern China. It is interesting to find that this flora presents more points of contact with Mesozoic vegetation than that of more western lands. Coming to the close of the Carboniferous period, the somewhat meagre *Glossopteris* flora of Gondwanaland is contrasted with the rich contemporary vegetation of the north; the latter is compared to the Dismal Swamp forest of Virginia, the former to the arctic vegetation of Greenland or Alaska. This comparison, though admittedly an exaggeration, brings out the relation of the *Glossopteris* flora to the extensive southern glaciation at that period. "A Scene in Gondwanaland" is pictured.

The chapter on the Triassic period is of special interest as it covers the transition from the Palæozoic to the Mesozoic vegetation, in some respects the most striking transformation in the history of the world's flora. While the earlier phases of the Triassic period were characterised by almost world-wide desert conditions, the abundant remains of plants in some Upper Triassic deposits indicate a renewed spread of forests. It is then that we discover the magnitude of the change in the facies of the vegetation since Palæozoic times. In the southern hemisphere, however, the two eras shade more gradually into one another.

The late Triassic and Rhætic floras show a rich vegetation, even comparable in some districts with the luxuriant forests of the Coal Age. The author inclines to the view that some Carboniferous types still persisted, regarding such genera as *Thinnfeldia* as probably Pteridosperms rather than true ferns. In coming to this conclusion, Prof. Seward is probably relying on work by Dr. Hamshaw Thomas not yet fully published. In Rhætic times the highly organised Cycadophytes, typical of the

Mesozoic age, first appear, while the maidenhair trees already occupied a strong position. "Before the end of the Triassic period the vegetation had put on a new dress, the dominant genera were of a much more modern type, and most of them bore no obvious marks of direct relationship to the trees in the Palæozoic forests" (p. 331).

In the succeeding Jurassic period, Mesozoic vegetation is seen in its most typical phase; fully developed, and not yet appreciably modernised. It was a period of stability, free from the violent movements of the earth's crust which disturbed the world both before and after. Though the Jurassic vegetation was not absolutely uniform throughout the world, it appears "less diversified and less affected by geographical position than that of any other stage in geological history" (p. 342).

Speaking of the great class of the Cycadophytes, the most characteristic plants of the era, the author rightly emphasises the total dissimilarity of Mesozoic and modern types of Cycads, as regards their fructification. He scarcely refers, however, to the evidence, scanty it is true, for the presence of a few Mesozoic Cycads of the recent family. Ferns, maidenhair trees, and conifers were other prominent groups at that period. The author suspects that even in the Jurassic some survivors of the old race of the seed-ferns still persisted.

Dr. Hamshaw Thomas's striking discovery of *de facto* Angiosperms (*Caytoniales*) is recorded. A critical discussion is postponed to the concluding chapter. The author seems scarcely to do justice to the hypothesis maintained by Wieland himself, and ably supported by Arber and Parkin, of an affinity between the Mesozoic Cycadophytes and the Angiosperms.

The Cretaceous period witnessed a profound change. While the Wealden, the oldest formation referred to this period, had an old-world flora, persisting from the Jurassic, "the late Cretaceous Floras are essentially modern, the flowering plants had already assumed the dominant position which they still hold" (p. 382). In Greenland, however, the oldest Cretaceous flora contains very modern-looking flowering plants (for example, magnolias, plane-trees, and bread-fruits) side by side with Cycadophytes, maidenhair trees and ferns still of a Jurassic type. Such facts have led to the hypothesis that Angiospermous vegetation came from the north. It is remarkable that the earliest Angiosperms, if rightly determined, belonged to well-characterised families, still flourishing in our own time.

Throughout the Tertiary period the dominant plants were Angiosperms, much as they are now. The author considers that "palæobotanical evidence supports the view that herbaceous flowering plants as a class are the more recent product of evolution", trees being older (p. 429).

The older Tertiary floras of North America and Europe point to the conclusion that from the beginning up to the early Pliocene, the climate was warmer than at present. This, however, does not apply to more eastern regions, where the fossils indicate a temperate, or even somewhat cold, climate in Tertiary times. The succeeding Ice Age destroyed most of our vegetation, and it has never quite recovered, though gardeners now endeavour to restore a few of the innumerable treasures then lost (p. 463).

There is a chapter on the Quaternary period, but this division of time is admittedly artificial—it is really the Tertiary continued. The occurrence of the great Ice Age is its only justification. Prof. Seward finds evidence that the destruction at that terrible time was not quite complete—a few species survived the cold.

The final chapter is devoted partly to questions of evolution, partly to the evidence for past climates. "Through the whole course of geological history . . . cyclic disturbances of the earth's crust were powerful factors in directing the course of evolution in the organic world" (p. 518). To such causes is due, for example, "the difficulty of discovering connecting links in the chains joining the Palæozoic to the Mesozoic world".

The evolution of the Angiosperms is left, as it must be, "an unsolved problem". Of Dr. Thomas's *Caytoniales* the author says: "They may be representatives of a branch from some ancestral stock from which was evolved, possibly at a later date, the whole Angiosperm alliance" (p. 521). He inclines to the view that possibly the Pteridosperms and the Angiosperms may be on the same line of evolution, an interesting hypothesis which may well be fruitful in leading to further research. "Evolution", he says, "has not been a simple progression; it has been a process of trial and error, a series of experiments" (p. 529).

The subject of the climates of the past is one long associated with the name of the author. The difficulties are serious and proportionate caution is shown. Yet the changes in distribution are so great and obvious that the palæobotanist is almost compelled to take refuge in Wegener's theory of continental drift.

The book concludes with an impressive passage on the æsthetic charm of the contemplation of the plant world, past and present. "The more we know the more conscious we become of the little we really know: the passion for the search grows as we read the story of creation" (p. 544).

Science at a New Angle.

Novius Organum: Essays in a New Metaphysic. By James Clark McKerrow. Pp. ix + 277. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1931.) 9*s*. net.

Mr. McKerrow says that his book exhibits "a heterodox metaphysic in relation to some scientific problems". In other words, he tries to see some old problems from a new point of view—one which is primarily scientific. But he differs from a good many students, in that he knows what to expect from science, and what not to expect. He perhaps under-rates his own acquaintance with scientific theory, in speaking of his knowledge as "very limited, second-hand and 'popular'". At any rate, the present volume is evidence that the author is able to handle difficult problems with an adroitness which argues grasp and originality.

One of Mr. McKerrow's objects is to solve the ancient dualism which regards necessity as being the law of inanimate Nature, whereas man is a law unto himself. He uses the conception of 'habit' to achieve this. "The appearance of necessity is either due to the relative fixity of habit, or is a statistical effect, or is due to the organisation of a system." An organism is "a system of habitual activity". The living creature is not something animated by habit; the habit *is* the organism, and the organism *is* the habit. Its essence is not substance but activity. Yet the biologist or physiologist, in his zeal for the study of structure, thinks in terms of "cross-sections of duration" and of events determined by conditions. According to the author, this is to think in terms of fictions.

Mr. McKerrow admits (p. 53) that his point of view often involves the profession not so much of beliefs as of various unbeliefs. He believes in 'activity' and 'habit', but not in 'cause', or in 'mind' (though he is not a behaviourist), or in 'events'. Even time is a useful and necessary fiction—"We do not live in time, we simply live and invent time to be lived through". Fictions are only dangerous, however, when they are taken seriously, and when the attempt is made to explain them in terms of fact—as when we seek physiological explanations of 'mind'. Similarly, "there is no explanation of 'mass', because it is a fiction invented to explain the behaviour of material bodies". As a matter of fact, the 'being' of a massive body is to move. "It enters into spatial relations, becomes aware, as it were, of being somewhere and naturally prefers anywhere else." The trouble with scientific explanations is that they mingle fact and fiction. "With diffidence we venture to suggest that the scientific superiority of Einstein's view over Newton's is due to the fact that it is more completely divorced from reality, Newton's time being comparatively real, the harmless, superfluous fiction, duration—and Einstein's a mathematical abstraction, a succession—a causal series ?—of cross-sections of duration. Fact and fiction ought not to be mixed."

This is a stimulating book, and is written in a vigorous and occasionally epigrammatic style. Most students of science will profit from reading it. They will be sure of meeting a number of ideas, a good many of them challenging some accepted notions. A study of the metaphysical side of his subject need not necessarily dispose the man of science to scepticism and distrust of his own methods. It will only teach him the useful truth that we cannot get more out of a pint pot than we put into it. "There is no such thing as mathematical truth; there are only right and wrong equations," says the author. This remark may have a wider application than we think.

J. C. H.

Short Reviews.

The Subject Index to Periodicals, 1929. Issued by the Library Association. Pp. x + 318. (London: The Library Association, 1931.) 70*s*. net.

The "Subject Index to Periodicals" issued by the Library Association is a valuable key to papers scattered among a large number of journals. Many of these papers, though containing useful information and suggestions, are in some danger of being overlooked because those interested in their subjects would not find any reference to them in the literature they are accustomed to read. Although the "Subject Index" is not confined to science, yet so large a number of subjects of interest to readers of Nature are dealt with, that the "Index" should be placed on the shelves in every good scientific library.

The "Index" was begun in the year 1915 and has since been published for every year with the exception of the years 1923–1925.

The present volume indexes the literature for 1929 as it appears in about 550 English and

American periodicals, 24 French, Belgian, and Swiss periodicals, 21 German and Dutch, and 2 Italian periodicals. It must not, however, be assumed that the "Index" is complete, even as regards English and American periodicals; for in order to avoid overlapping, and also to restrict the size, no attempt has been made to index periodicals covered by certain named publications, such as *Science Abstracts*, sections A (Physics) and B (Electrical Engineering), *Journal of the Society of Dyers and Colourists*, *Revue de Géologie, Minéralogie et Crystallographie*, etc.

We do not think that the exclusion of papers already indexed in publications readily accessible to the scientific investigator will be considered a disadvantage. In any event, the "Index" for 1929 contains references to some 24,000 articles arranged under alphabetical subject headings. Verse and fiction are excluded from this catalogue.

The general editor is Mr. E. E. G. Tucker, who has been assisted by a very large number of voluntary contributors, including the chief librarians and staffs of a large number of important British libraries.

Astronomy: an Introduction. By Prof. Robert H. Baker. Pp. xix + 521. (London: Macmillan and Co., Ltd., 1930.) 16s. net.

This book is intended for use as a text in introductory college courses in astronomy. It covers a very wide field, but the subject is so large that, in spite of the considerable size of the volume, only the most cursory treatment of the material is possible. Problems of practical astronomy, as the preface states, have for this reason been almost entirely excluded. Bearing this general and inevitable characteristic of the book in mind, it may be recommended as a thoroughly sound and well-constructed textbook, as far up to date as the time of publication allowed, and enriched by a large number of excellent, well-chosen, and well-reproduced illustrations. It demands little previous knowledge of physics or mathematics, and is clearly and interestingly written.

The economy in expression is well exemplified by the title. Roughly about half the book is devoted to the solar system and the remainder to the stellar universe—perhaps a fair distribution of space among applicants to consideration whose claims are of such widely different character. As a reference book it will be of value to a much larger public than that formed by elementary college students. The only point of criticism serious enough to refer to relates to the method of numbering the paragraphs. Each paragraph is indicated by the number of the chapter containing it, followed, after a dot, by the serial number of the paragraph in that chapter; for example, 11·16 is the 16th paragraph in chapter 11. This is quite clear when the system is grasped (it is not explained in the preface), but the dot is so reminiscent of a decimal point that one would naturally expect to find 11·16 before 11·3, and accordingly may fail to locate a reference. This defect should be remedied in some way in future editions.

A Manual of the Slide Rule: its History, Principle and Operation. By J. E. Thompson. Second printing. Pp. vii + 220. (London: Chapman and Hall, Ltd., 1931.) 5s. net.

Many users of the slide rule will be surprised to find that it can provide enough material for a book of 220 pages.

The first of the five chapters is perhaps the most interesting; in it the history of the slide rule is given in full. Most of the information in Chap. ii., which deals with the elementary theory and operation of the slide rule, will be familiar to many users of the instrument.

The remaining chapters of the book deal with special forms and typical settings of the slide rule. In this part of the book the solution of right-angled and oblique triangles is explained. This particular use of the slide rule is of special interest in gunnery and the solution of the *BOT* triangle might have been included. Incidentally, the solution of triangles deserves a place in Chap. ii., for most readers will be more interested in the first two than in the remaining chapters.

The Treatment of Chronic Deafness by the Electrophonoïde Method of Zünd-Burguet. By Dr. George C. Cathcart. (Oxford Medical Publications.) Second edition. Pp. xiii + 111. (London: Oxford University Press, 1931.) 5s. net.

The successes obtained by Dr. Cathcart in the treatment of 665 cases of deafness by re-education are of peculiar interest to otologists and to patients with this crippling affliction; he obtained definite improvement in three-quarters of his cases of nerve-deafness, two-thirds of the cases of chronic otitis media, and in a half of the cases of otosclerosis. The treatment involves one or two exercises of five minutes' duration daily. He used the electrophone as the source of sound; this is an electro-mechanical oscillator of the vibrating reed type, with controls for variation of pitch and intensity. Nowadays, an audio-frequency oscillator incorporating two or more thermionic valves would be found easier to handle, but the arrangement of the exercises might well follow the plan of Dr. Cathcart, which has already proved so successful.

An Elementary Course in General Physiology. Part 1: *Principles and Theory.* By Prof. G. W. Scarth. Part 2: *Laboratory Exercises.* By Prof. F. E. Lloyd and Prof. G. W. Scarth. Pp. xxi + 258. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1930.) 13s. 6d. net.

The best avenue of approach to the study of biology and medicine is by way of the physical chemistry underlying the general principles of plant and animal physiology. For students who have not had the advantage of a preliminary training in physical chemistry, the first part of this book, which is written by Prof. Scarth, will just supply the deficiency. The second part of the book, under the combined authorship, provides a course of carefully planned laboratory exercises in general physiology suitable for class use.

Faraday Centenary Exhibition.

WITH the possible exception of Italy, which in 1899 and 1927 organised the notable exhibitions to commemorate, first, the centenary of the invention of the voltaic pile, and secondly, the centenary of the death of Volta, no country, we believe, has arranged so interesting and striking a display of scientific instruments, apparatus, and appliances in honour of one man as that which is to be seen in the Faraday Centenary Exhibition at the Albert Hall, formally opened by the Right Hon. J. C. Smuts on Sept. 22, just after his inauguration as president of the British Association.

It is in every way an exhibition worthy of the man and of the occasion. But however important we may regard Faraday's discovery of electromagnetic induction which has given rise to the present celebrations, and however much interest may be felt in the apparatus with which he made that discovery, the exhibition as a whole is an eloquent reminder that the world's debt to Faraday is not confined to a single discovery in one branch of science, but to that very remarkable series of investigations which, spread over more than a quarter of a century, opened up new fields of inquiry and led to an immense increase of natural knowledge and of its application to the needs of mankind. That the origin of so many of the most important developments in communication, transport, and industry can be traced to the work of a single man is an extraordinary tribute to the genius of Faraday, and whether the visitor starts with an inspection of the inner circle of exhibits, which illustrate the various branches of Faraday's researches, and then proceeds to examine the outer circles of exhibits where the modern developments are shown, or reverses the order of his examination, he cannot but be impressed with the truth of the statement, so often made, that Faraday was the greatest experimental philosopher the world has ever seen.

The arrangement of the exhibits is simple and admirable. In the centre on a raised platform stands a replica of Foley's statue of Faraday which is in the Royal Institution, and around this are grouped some of Faraday's apparatus and his notebooks, diaries, manuscripts, and letters. From this platform radiate eight avenues, between which, in three concentric circles, are arranged twenty-four stands, the inner eight of which illustrate Faraday's various researches, while the remaining sixteen are devoted to the branches of industry and science which owe so much to his original work.

The display of Faraday's apparatus and the illustration and demonstration of Faraday's inquiries have been arranged by the staff of the Royal Institution, but the exhibits of apparatus and machinery on the other stands have been arranged by various institutions and organisations connected with the electrical and chemical industries. Like all the events arranged in connexion with the Faraday centenary celebrations, the exhibition is a result of the co-operation, in the first place, of the Royal Institution and the Institution of Electrical Engineers, but the exhibition as a whole has been the work of the Exhibition and Publicity Sub-Committee, of which Lieut.-Col. W. A. Vignoles is the chairman and Mr. J. I. Bernard, of the British Electrical Development Association, is the secretary. Col. Vignoles is also the editor of the Souvenir Catalogue and Guide.

It has often been remarked that many of the most important discoveries in science have been made with the simplest of apparatus. The truth of this is exemplified by the work of such as Wollaston, Hughes, and Rayleigh, and it is well illustrated by many of the relics of Faraday's work as shown in the exhibition. Foremost among the relics is, of course, his iron ring with which he made his discovery of Aug. 29, 1831. Of this a large model is also shown, which, though it does not actually function, is made to appear as if it did so, thus enabling his experiment to be repeated on a scale suitable for the public to see. Many other pieces of apparatus are shown in the glass cases around the central platform, and then come the eight stands devoted in turn to electric science before 1831, Faraday's discoveries in 1831, effects of induced currents, Faraday's researches in magnetism, Faraday's researches in chemistry, Faraday's researches in electro-chemistry, Faraday's researches in electrostatics and the electric discharge. Each stand is lettered, each exhibit numbered, a staff of voluntary demonstrators is present to explain and demonstrate, and in the excellent Souvenir Catalogue and Guide are a valuable series of extracts from Faraday's writings, together with descriptive notes. The books shown include volumes of his Diary laid open at interesting pages, his MS. notes of Davy's lectures, a part of the MS. of Faraday's "Chemical Manipulation", and his Commonplace Book. Some of his medals and orders are also on view.

PHYSICAL AND ENGINEERING EXHIBITS.

Leaving the exhibits intimately associated with Faraday, the visitor has a choice of examining the interesting collections of telegraphic or telephonic apparatus, electrical measuring instruments, dynamos, X-ray apparatus, and of plant used in the chemical and metallurgical industries, and for the generation and transmission of electricity, and for communication and broadcasting.

The displays illustrating the generation of electricity, electrical measurement, and transformers have been arranged by the British Electrical and Allied Manufacturers' Association (Inc.). Many of the early magneto-electric machines and dynamos are shown, including the little-known generator built by Woolrich of Birmingham in 1844 and used up to 1877 for electroplating. This appears to be the first industrial generator. The main exhibit, however, is a large model of a complete generating, transforming, and switching plant with a pulverised coal-fired boiler and a 25,000 kw. turbine.

On the stand illustrating the development of electrical instruments and transformers there are nearly 300 exhibits, dating from the early electroscopes down to the most modern instruments. They are grouped in chronological order, and contain examples of the work of many famous investigators.

An exhibit which will attract much attention is that arranged by the Electric Lamp Manufacturers' Association of Great Britain, Ltd., to show in as simple a form as possible the principal stages of lamp manufacture. The operations include the coiling and insertion of the filament, the sealing in, and the exhausting of the lamp of air. In the latter operation it is of interest to note that after the exhaustion of the air the bulbs are 'washed' out several times with nitrogen, and argon is then admitted to about half atmospheric pressure.

The transmission and distribution of electricity is illustrated by a series of exhibits arranged by the Cable Makers' Association; the Central Electricity Board has placed on view a large coloured map showing the complete 'grid' transmission system in Great Britain; while electricity in transport is illustrated by models of electric locomotives, flying boats and aeroplanes, signalling apparatus, and a model of the s.s. *Viceroy of India*, the first turbo-electrically-driven vessel in the British mercantile marine. Electricity in the home and electricity for industry, in both of which electrical heating plays a chief part, are illustrated by displays of exhibits on two stands arranged by the British Electrical Development Association.

In the use of electricity for communication, first came land telegraphy, then submarine telegraphy, followed many years afterwards by wireless telegraphy, wireless telephony, and broadcasting. These are the sections in the exhibition which the General Post Office and British Broadcasting Corporation have arranged. The exhibits occupy the four stands *W*, *X*, *Y*, and *Z*. On *W* Stand the B.B.C. has arranged the actual transmitting units forming a part of a regional transmitting station capable of supplying a power of 75 kw. to its aerial system and of giving a nearly equal response to all frequencies between 30 and 8000 cycles per second; while another exhibit in three sections shows modern improvements in valves for radio broadcast reception. Stand *X* of the Post Office is devoted to telegraphy. About half the exhibits here have been provided by the Imperial and International Communications, Ltd., and relate to submarine telegraphy. Among the other half of the exhibits is a working and true reproduction of the electromagnetic telegraph installed by Gauss and Weber at Göttingen in 1833, which has been presented to the Institution of Electrical Engineers by the Elektrotechnischer Verein, Berlin, as a tribute to the memory of Faraday. Further exhibits of submarine cables are shown on Stand *Y*, where are also to be found an automatic telephone equipment and radio apparatus. One notable exhibit is the five-hundred-kilowatt thermionic valve manufactured by the Metropolitan Vickers Electrical Co. for the Post Office for use at Rugby. Described as "probably the most remarkable achievement in the development of wireless communication since the introduction of the three electrode thermionic valve in 1907", the valve is designed to handle the enormous output of 500 kw., thereby replacing fifty ordinary high-power valves in the main Rugby transmitter. Made mainly of steel, copper, and porcelain, standing ten feet high, and weighing more than a ton, the valve is "a robust piece of engineering construction". Needless to say, its construction has only been rendered possible by that scientific research of which the whole exhibition is indeed the fruits. Side by side with these notable exhibits is a display of X-ray apparatus arranged by the Institute of Radiology; while on Stand *Z*, also arranged by the General Post Office, are further exhibits connected with telephony and wireless telegraphy.

Two other features in the exhibition may be briefly referred to. Many scientific workers in the past have made their experiments in kitchens and cellars and the like. Faraday's work, in the main, was done in the stone-floored basement of the Royal Institution. What that old laboratory was like is known from the water-colour drawing made of it in 1852 by Miss Moore. The laboratory has undergone many alterations, and the numerous bottles containing Faraday's chemicals and much of his apparatus have long since disappeared. But enough information has been forthcoming to enable a reproduction of the laboratory to be made, and thanks to the labours of Mr. Malcolm, the director, and of the staff of the Wellcome Historical Medical Museum, visitors to the exhibition can now picture in what surroundings Faraday made his discoveries. The reproduction of the laboratory has been arranged in the King's Room, on the first floor of the Hall.

Another interesting feature of the exhibition is that of the admirable system of lighting and decoration. From the roof of the building has been suspended a great roof canopy or velarium of cotton dyed primrose and cream. On to the under side of this the light from 200 concealed projectors is thrown, each projector having a 1000-watt lamp, and the hall is thus illuminated throughout by the light reflected from the velarium. A great tubular lantern also hangs in the centre of the hall, while there are half lantern lights on the pilasters. The result is that every exhibit is adequately illuminated, while the effect throughout is pleasing and restful.

CHEMICAL EXHIBITS.

The organisers of the Faraday Centenary Exhibition did well to devote a portion of the space available at the Albert Hall to the commemoration of Faraday's chemical labours and to a demonstration of some of their fruits. Faraday was first and foremost a chemist; it was the fascination of chemistry which drew him to Davy and to the Royal Institution. By way of his epoch-making studies in electrochemistry, to which a stand is devoted, he climbed to the heights of his achievements in the study of electricity and magnetism. His greatness as a physicist rested on a secure chemical foundation. Nowadays we surfeit our physicists with quantum theory and relativity and starve them of chemistry. Thus trained, how can they have a balanced outlook on natural phenomena? It would be well if some of our universities took Faraday's career to heart in mapping out the training of their students.

As Sir William Bragg said at the Queen's Hall in his eloquent eulogy, Faraday had a flair for fundamentals. This is revealed as much in his chemical as in his physical work. Whatever he touched—optical glass, alloy steels, rubber, sugar from beet, oil products—is a century later of first importance. His heavy lead borosilicate glass achieved importance at the time, and is of historic interest, since with a piece of it Faraday discovered diamagnetism, thereby breaking down the apparently insurmountable barrier between magnetic and non-magnetic substances. In his researches on alloy steels he was ahead of his time. Alloying iron with chromium, nickel, and some of the precious metals, he foreshadowed much of the modern work which has resulted in the production of all kinds of alloys essential to many latter-day engineering triumphs.

The annual world consumption of special steels to-day is five to six million tons. An aircraft engine may have as many as seven different kinds of alloy steels used in its construction, containing nickel, chromium, vanadium, and molybdenum in varying proportions, all specially adapted to the tasks they have to perform in different parts of the structure. Among the many achievements illustrated at the Albert Hall are the manganese steels, developed by Hadfield in the early 'eighties, heat-resisting steels, high electrical resistance steels (containing aluminium, chromium, and nickel), non-magnetic steels (containing manganese, nickel, and chromium), cobalt and tungsten steels for permanent magnets, tungsten steels for high-speed tools, and finally stainless steel and iron, the housewife's boon, the development of which goes from strength to strength.

From the discovery of benzene to the latest commercial dyestuff is a long and brilliant stage in the progress of chemistry. The whole edifice of organic chemistry has been built up in this period—surely one of the greatest achievements of the human intellect. It is difficult to put ourselves back into Faraday's condition of chemical thought, so secure are we now in our knowledge of the structure of organic compounds. He discovered benzene, the fundamental substance of hundreds of dyestuffs, of drugs, antiseptics, explosives, even of the secretions of the glands which regulate the functions of our bodies. The figure of Faraday, under the dome of the Albert Hall, appears to gaze with appreciation at the brilliant array of colours "at the sign of the Hexagon", illustrating how from benzene and the other constituents of coal tar, succeeding generations of chemists have conjured dyestuffs of every hue for every kind of material. Our veteran chemist, Prof. H. E. Armstrong, conceived the idea of exhibiting these marvels, not in uninspiring bottles, but in their brilliant hues on delicate fabrics.

Never before, we believe, has it been made possible at a public exhibition in this way to trace the history of dyestuffs and follow the development of colours in terms of structure. More than a hundred different dyestuffs are shown. It is hoped to transfer this exhibit, which has been got together at great pains, and could not have been assembled at all without the generous assistance of a number of colour-making and textile firms, to another temporary home in South Kensington before it is dispersed.

Faraday, as is well known, discovered benzene, which he called bicarburet of hydrogen, in 1825, in the oil which accumulated in cylinders of compressed oil gas, made in the early days of gas-lighting by decomposing at a red heat—as we should say, cracking—whale oil. He isolated the crude benzene by fractional distillation, purified it by freezing, and determined its composition and vapour density. Not until twenty years later was it detected by Hofmann in coal tar, from which it is now obtained in millions of gallons annually. Faraday observed the almond-like odour when nitric acid acts upon benzene, but Mitscherlich first isolated nitrobenzene in 1834. Zinin first reduced nitrobenzene to a base, which he called benzidam, in 1841, and in 1845 Hofmann showed that this was identical with a base, aniline, obtained by Fritsche, also in 1841, from indigo. Thus was the relationship of benzene to a colouring matter first established. Nevertheless, it took Bayer twenty years to settle the constitution of indigotin, the colouring constituent of indigo. Many years of further research were required to establish the manufacture of indigotin as a commercial success; though its manufacture was commenced in 1881, it was not really successful until near the end of the century.

This, however, is a digression. Faraday has another claim to the homage of dyestuff chemists. In 1826 he discovered the two sulphonic acids of naphthalene, which he described in a communication to the Royal Society as sulphonaphthalic acids. This work is little known, but it very probably had considerable influence on the trend of investigation into the action of sulphuric acid on organic compounds. Reading Faraday's paper, one marvels at his skill in detecting the two acids, distinguishing them by the solubilities of their barium salts and the manner in which these burned. He worked out the whole technique which we still use for isolating sulphonic acids, analysed the two, and concluded that they had the same constitution. The phenomenon of isomerism had been discovered just before by Liebig and Wöhler (silver fulminate and silver cyanate), and Faraday had himself recently shown that acetylene and bicarburet of hydrogen (benzene) had the same empirical composition. He does not stress the point of the isomerism of the two sulphonates, but he makes a very shrewd guess at the mechanism of the sulphonation process, as we now call it. These two sulphonic acids are, of course, of first-rate importance in the dyestuff industry, the β-acid being the source of β-naphthol, one of the most important dyestuff intermediates. Sulphonation is used for rendering all classes of dye soluble in water.

The history of the development of dyestuffs, from Sir W. H. Perkins' discovery of mauve in 1856, by oxidising crude aniline from coal tar by means of sulphuric acid and bichromate, down to the latest discoveries of modern times, is extraordinarily well told in the catalogue of the exhibition. Perkins' mauve was a beautiful shade on silk (a dyeing of a preparation made by Perkin himself is shown), but it is fugitive and became superseded by better dyes. The primitive artificial dyes were safranine, the magentas, and the Manchester group (aminoazobenzene, Bismarck brown, Manchester yellow), then followed Witts' chrysoidine, the tropæolins, azo scarlets, and reds (from β-naphthol). A sensation was caused by the direct cotton dyes (1884), then followed the gay but fugitive triarylmethane dyes. Synthetic alizarin and some of its congeners were developed by Perkin in England and also by German chemists; later came the fast acid anthraquinone dyes, to be followed at the beginning of the twentieth century by the wonderfully fast anthraquinone vat dyes. Jade green, the most brilliant and fast of this series, is a British post-War development, as is also an improved form of indanthrene blue, the great discovery of Bohn. The indigoid dyes, sisters and cousins of indigo itself, in shades of yellow, blue, red, and violet, form a gay quartet and arouse speculation as to the influence of constitution on colour. In this connexion there is a remarkable series of dyes of the indolenine series, basic dyes containing two substituted indolenine groups joined by a chain of $(:\mathrm{CH}\cdot)_n$ groups. When $n=1$ the colour is yellow; $n=3$, pink; $n=5$, blue; $n=7$, green. In other words, in this series an absorption band moves right across the visible spectrum as the length of chain increases. This series will interest students of the carotin series of natural dyes. Finally, mention must be made of Prof. Robinson's exhibit of preparations of synthetic flower colours and their chemical relationships.

Power.*

By Sir Alfred Ewing, K.C.B., F.R.S.

To explain the task of the Bramwell lecturer we must recall the meeting of 1881, when the Association was celebrating its jubilee in the heyday of Victorian prosperity and confidence. It was a jubilant jubilee. Never, perhaps, was applied science more actively progressive. From day to day its achievements compelled attention. Electricity was knocking at the door, bringing a wallet big with gifts, wonderful gifts that established new contacts between the sciences of the laboratory and the arts of social life.

Think for a moment of what the late 'seventies and the early 'eighties gave to mankind. The telephone, the phonograph, the incandescent lamp, the dynamo in a practical form, the electric motor, the storage battery, the transformer, the internal combustion engine using liquid fuel, cold-storage and refrigerated transport of food, the idea of public electric supply, the use of alternating currents, the first clear recognition of the potentialities of electricity as an agent for lighting, for traction, for the conveyance and distribution of power. There, indeed, was a dish to set before the potential rulers of a kingdom which was waiting to be explored, where every engineer in the bud might well fancy himself to be a coming king.

> " Bliss was it in that dawn to be alive,
> But to be young was very heaven."

Among those fertile years I would specially mention 1881, which was the date of Bramwell's prophecy as well as the jubilee of the British Association. Apart from that, it marks an epoch. For the world then realised that a problem was at last solved with which it had been much concerned, the problem called the subdivision of the electric light. Before that the electric light had meant the electric arc—a dazzling unit, brilliant, overpowering, capricious, admired out of doors, but quite unfitted for the home. It was a tiger burning bright which declined to become a domestic pet.

Then came Edison and Swan, who, working separately, taught us how to tame it by inventing the incandescent filament enclosed within a vacuum bulb. Near the end of 1881, Sir William Thomson (as he then was) lighted his house in Glasgow by means of Swan's lamps. For prime-mover he chose the new gas engine of Dugald Clerk, which completed its cycle in two strokes, unlike the already familiar Otto engine, which required four. Clerk's engine was itself a novelty the importance of which we have come to recognise. To this day all internal combustion engines use either the Clerk or the Otto cycle, and for large powers the Clerk cycle has advantages which tend to give it the favoured place.

Fifty years ago the gas-engine was much in the public eye. No engineer who gave the matter serious thought could fail to see the advantage of having heat developed within the working substance itself instead of being conveyed to it by conduction through a containing shell. Another obvious merit of internal combustion was one that Carnot had recognised in the immortal little treatise where he laid the foundations of thermodynamics—the advantage which you secure by supplying heat to the working substance at a much higher level of temperature than can be reached with steam. Finally, there was this broad difference: the gas engine had the indefinite promise of youth;

---

* From the presidential address to Section G (Engineering) of the British Association, being also the Bramwell Trust Lecture, delivered in London on Sept. 25.

the steam engine was an old servant the limitations of which were well known. Nobody expected that steam would change its ways. Small wonder then that the engineers of those days looked to the future of the gas engine with exaggerated hope.

It was in that spirit that Bramwell made the prophecy we have now, after fifty years, to review. At the jubilee meeting in 1881 he gave an address "On Some of the Developments of Mechanical Engineering during the last Half-Century". It reviews a great field with the lucidity of which he was a master, dealing specially with applications of the steam engine, and it includes a section relating to the transmission of power. Electrical transmission is barely touched on: it had, in fact, scarcely begun; but he speaks of transmission of power by means of gas, and in that connexion he remarks:

"I think there is a very large future indeed for gas engines. I do not know whether this may be the place wherein to state it, but I believe the way in which we shall utilise our fuel hereafter will, in all probability, not be by way of the steam engine. . . . I very much doubt whether those who meet here fifty years hence will then speak of that motor except in the character of a curiosity to be found in a museum."

Bramwell returned to the question when president of the British Association in 1888. In his address he repeated the forecast of 1881, and added: "I must say I see no reason after the seven years which have elapsed since the York meeting to regret having made that prophecy or to desire to withdraw it". It is evident that he took his 'prophecy' very seriously. He was the acknowledged sage and spokesman of the engineering profession, occupying, in that regard, a unique position, such as no one could possibly hold in the more complex conditions of to-day. He was a humorist, and doubtless there was a conscious touch of humorous exaggeration in what he said; but for all that it was an engineering judgment delivered *ex cathedra*, and his judgments were accustomed to command respect.

Finally, when within a few months of his death, at the age of eighty-five years, he wrote to the president of the British Association, saying that he wished to keep alive the interest of the Association in this subject, and for that purpose offered a sum, which was to be paid as honorarium in 1931 "to a gentleman to be selected by the Council to prepare a paper having my utterances in 1881 as a sort of text, and dealing with the whole question of the prime-movers of 1931, and especially with the then relation between steam engines and internal combustion engines".

That is the task I am now attempting to discharge. The prediction has, in great measure, failed to come true. Steam is neither dead nor dying. To-day, it is a much more efficient medium than it was for the conversion of heat into work, and we find it actuating engines of vastly greater individual and aggregate power than any that were even imagined when Bramwell spoke. But alongside of that we have wonderful achievements on the part of the internal combustion engine which go far to justify the enthusiasm that stirred him fifty years ago.

Looking back now, one is amazed at the boldness of his prophetic outlook. It was more than bold; it was almost foolhardy. Remember that he had nothing to go by except the performance of the gas engine, and that only in very small powers. Gas, whether the ordinary illuminating gas distilled from coal, or the cheaper product of the Dowson process, was the only fuel then in practical use for internal combustion. The oil engine in its various forms, the petrol engine, the Diesel engine—these were still to come.

The success of the Otto gas engine led makers to design engines operating in much the same way, but using for fuel a spray of oil instead of gas. Such engines found a place where gas was not available, as in the driving of agricultural machinery. For the most part their fuel was the safe and familiar oil of the paraffin lamp. Like the gas engine, they were heavy and they ran at very moderate speeds, such as 200 revolutions per minute. About 1883, Gottlieb Daimler set himself to produce an engine with much lighter working parts which should run at a far higher speed, five times as fast, or more, and should use for fuel an oil so volatile that a carburettor would serve to charge the incoming air with combustible vapour. After successful trials with a bicycle he applied his motor, in 1887, to drive a car on the road. That was the beginning of a new era in locomotion. The world discovered in Daimler's petrol engine an appliance such as it had not possessed before—a light, convenient, inexpensive prime-mover, yielding amounts of power which were ample for road vehicles, easy to start and stop and regulate, demanding little attention and no particular skill. Before long it gave city streets an altered character and country roads an unsuspected value. Man acquired a new mobility which changed his notions of distance and of time. In due course the petrol engine also achieved the conquest of the air. At the end of 1903, only a few days after Bramwell's death, the brothers Wright took their first flight in a motor-driven aeroplane. It is the petrol engine that must bear the responsibility—the grave responsibility—of having made it possible for man to fly.

The era of the road-motor began with Daimler's experiment of 1887, but a good many years were to pass before it took the dominant position it holds to-day. The horse was already in possession, and did not yield without a struggle. That sensitive animal had a frank dislike of the horseless car. To meet his objections our legislators ordained for mechanically-driven vehicles a speed not exceeding 4 miles an hour, and required each of them to be in charge of three persons, one of whom should carry a red flag in front. Not until 1896 was the Red Flag Act repealed. The sinister emblem has gone, and the horse has nearly gone too. But engineers will not let his memory perish. Thanks to the initiative of James Watt, they treasure his name in one of their most necessary words. The horse may become little more than an instrument of sport or an excuse for betting, but it is safe to say the horse-power will never die.

About 1895, Rudolph Diesel initiated another epoch-making change. Instead of compressing a combustible mixture, he compressed the air alone, bringing it to a very high pressure, and thereby making it so hot that when the charge of oil was forcibly injected at the dead-point there was instant ignition. This escaped all risk of pre-ignition and greatly augmented the efficiency of the action, as a thermodynamic consequence of the very high temperature at which the fuel gave up its heat. To force the fuel in, he at first employed an auxiliary supply of still more highly-compressed air, but this plan is now less common than the simpler one of using a high-pressure pump, which delivers the oil in a spray of exceedingly fine drops. The essential feature of the engine is that the fuel does not enter the cylinder until the air there is highly compressed and the working stroke is about to begin. It is this feature which has made the Diesel engine the most efficient of all known means of obtaining mechanical work from the combustion of fuel.

Imagine our prophet of 1881 brought back to earth so that he may see for himself in what measure his expectations have been fulfilled. He will come, of course, by aeroplane, and on the way the pilot will tell him of the part which the internal combustion engine played in the War; of submarines and road-motor transport, and tanks and aircraft. He will be told of Zeppelins and air-raids, of the horrible superiority of attack over defence that characterises modern war. He will learn how prodigiously man has increased his power to kill his fellows and destroy their works. The old gentleman will be saddened to think that the world owes this to engineers, and especially to the internal combustion engine. It will grieve him to reflect that the island safety of England has departed, never to return. On the other hand, he will be told of air-mails to India and Australia and the Cape, and it will interest him much to learn that the engine which is bringing him so swiftly and comfortably to earth weighs no more than a couple of pounds per horse-power, and that engines of the same type, but lightened and tuned to the uttermost for racing, can develop more than a horse-power for every pound of weight. He will hear, perhaps with less enthusiasm, of speed records by air and sea and land, amazing records which are set up only to be broken. "Brief life is here our portion" might be said of the records, and also, alas, of many of the record makers and record breakers. As he approaches London our aerial voyager will note the highways thick with motor-cars, coaches, and lorries, and will wonder for a moment what has happened to the railway shares he left behind, doubtless selected as a secure investment of the terrestrial fruits of his industry and thrift. For in Bramwell's time there were still people who practised these now exploded virtues, and there were even Chancellors of the Exchequer who encouraged them.

We may imagine that the pilot brings him over the river and the docks, where he may see big motor-ships like the Nelson liners arriving with their frozen or chilled cargoes. One of his pet bits of engineering was mechanical refrigeration, and he will take particular satisfaction in noticing ships that are not only driven but also cooled by internal combustion engines. From the docks they will proceed over the City, where at every crossing he will observe the congestion of motor-cars and taxis, and the multitudinous motor-bus—but never a 'growler', which was the vehicle he used to favour. I well remember his taking me to visit a cold store on the south side of the river; we were on our way in a 'growler' when the bottom fell out and we were left sitting in the road. He was, as I have hinted, no light weight; my part in the comedy was only that of the last straw. The cab stopped without injury to life or limb, Bramwell forming an effective automatic brake. His genial dignity suffered no eclipse. His spirits were undamped—and his person too, for luckily the street was dry.

Finally, let us think of the pilot bringing him over Waterloo Place to revive his memories of the beloved club where he used to spend many placid hours. Below him will be the Athenæum, more than ever a haven of rest for the mature, but now on the outer edge of a vortex which is fed by torrents of one-way traffic from the Haymarket and Trafalgar Square—a veritable inferno of internal combustion—an inferno that would be intolerable were it not tempered from time to time by authoritative outstretchings of the arm of the law. As he watches the maelstrom, and perhaps sees a bishop trying to reach the club, he will thank the fate which has removed him from the present-day terrors of the pedestrian, from compulsions to unseemly agility and temptations to unseemly profanity. Such temptations are, of course, only for laymen, but life in Waterloo Place, even for bishops, must sometimes be furious as well as fast.

When all these things have been seen, we must not imagine Bramwell posing as the satisfied prophet who complacently remarks "I told you so". He had too judicial a temper for that. He would want to know about other users of power, and would ask many questions. What about our navy, and other navies, the biggest liners, the railways and the great factories, and the coal pits with their plant for winding and ventilating, and what about the distribution of light and power from central stations—on what kind of prime-movers do these rely? And the answer would be steam, and steam, and yet again steam. He would soon learn that steam still does a great part of the work of the world, and that one need not go to the Science Museum at South Kensington to find specimens of its remains. But if he did go to the Science Museum he would see admirably displayed there some remarkable engines. Side by side with the mementos of Newcomen and Watt, those fascinating heralds of the dawn, he would see engines of a far more recent type enshrined in the honour they so well deserve, not as relics of an obsolete past but as precursors of the modern era which was opened to the world by the genius of Charles Parsons. For among the treasures of our national museum of science is Parsons' first steam turbine, which dates from 1884, the first turbine to which he fitted a condenser, which dates from 1891, and also a part of his famous little craft, the *Turbinia*, by which in 1897 he demonstrated the applicability of the steam turbine to the propulsion of ships.

These dates are all subsequent to Bramwell's prophecy of 1881. Many factors have contributed to prevent that prophecy from being fulfilled, but none has been so potent as Parsons' development of the compound steam turbine. That invention was no mere throwing out of a happy thought. It was the life-work of a man who, to an extraordinary degree, combined creative imagination with energy and persistence and practical skill.

Such a man lives on in his achievements. To Parsons it was granted as to few men to see the fruit of his ideas and his labours. Long before he died the world recognised that he had revolutionised steam engineering. He had taught us how to generate power on a scale and with a concentration never before approached. Nothing, in a sense, could be simpler than his steam windmill with its successive rings of vanes, each in turn taking up a small fraction of the whole energy of the blast. To conceive such a device was one thing, to give it being and action was quite another. That meant many subsidiary inventions and years of toil; it meant the removal of mountains of prejudice and difficulty. But the triumph is complete. Engineers, all the world over, are whole-heartedly converted. They build their steam windmills on a colossal scale, crowding 50,000 or 100,000, sometimes even 200,000 kilowatts into a single unit, confident in the knowledge that no more trustworthy and economical prime-mover is available for the gigantic stations which play so important a part in modern civilisation as centres for the production and distribution of light and of power.

Review the great power stations of the world, and you find their method of manufacturing electric energy from heat is almost wholly through the medium of steam. To illustrate how small a place is taken in them by the internal combustion engine, let me quote some figures for British power stations. A return published in 1930 by the Electricity Commissioners gives the aggregate capacity of the generative plant of various types as follows:

	Kilowatts.
Steam turbines	5,531,952
Reciprocating steam engines	138,806
Oil engines	71,331
Gas engines	17,473
Water-power plant	42,208

Oil engines and gas engines together make up only 1½ per cent of the whole. Abroad, as well as at home, the steam turbine is dominant.

It is in great power stations equipped with large turbines and coal-fired boilers, using steam of high pressure and high superheat, that we find the most economical production of power from fuel. A modern turbine can generate one electrical unit with a consumption of barely 1 lb. of cheap coal, which means that it converts into electrical energy fully 30 per cent of the potential energy of the fuel. The internal combustion engine finds little favour in power stations, save as a stand-by to assist occasionally in meeting the peak load.

Turning now to another field, we find that in railway traction the supremacy of steam is maintained. Much attention has been paid to the Diesel engine as a possible alternative, but so far the number of Diesel locomotives that have found employment in main-line working is a negligible proportion of the whole. If the steam locomotive is to disappear, there is no indication that its place will be taken by an internal combustion rival. What is much more likely is that it will in time be driven out—wholly or in part—by electric traction, as Lord Weir's Committee has recently suggested for the British railways. But electrification will mean that the prime-mover is still steam, though acting at a central station—except, of course, in countries which have available reserves of hydraulic power.

Such a country is Switzerland, and there the transformation from the steam locomotive to electric traction is already almost complete. The playground of Europe has lost little or nothing of its charm through becoming dotted with hydraulic power houses. Already its exports to less favoured neighbours include many million units of electric energy, which it delivers through the graceful catenaries that girdle its mountains and span its valleys. The shrewd inhabitants doubtless demand a remunerative price for exported electricity, just as they quite properly do for the other amenities of their delightful land. A time may come when subterranean stores of coal and oil run low, but, so long as the sun shines and the rain falls, mankind will be able to continue its struggle for existence, though it may suffer a change in the centre of gravity of its industrial life. Industry will learn, like the Psalmist, to look to the hills whence cometh its help, and Geneva will be more than ever the natural rallying point of a community of nations, physically linked by a comprehensive 'grid' on which they depend for whatever modicum of light and power they are still permitted to enjoy.

For road motors, and for the air, the internal combustion engine is, of course, supreme; it has created as well as supplied a vast demand. We ought, I think, to pay tribute to the constructive talent that has made these engines the convenient and reliable prime-movers they have in fact become.

Turning to the field of ocean navigation we find a situation which is puzzling, unsettled, and difficult to analyse. For in the selection of prime-movers for ocean-going ships, there are sharp differences of opinion and of practice; there is no sense of finality; there is even—so it seems to me—a good deal of fashion and caprice, and of the probability of change which one associates with such moods of the mind.

In our own navy and foreign navies there is a practical monopoly on the part of steam, except, of course, in submarines. But the mercantile marine is in a state of flux. Before the War there were almost no motor-driven ships. The *Selandia*,

Book No.....
LIBRARY

which dates from 1912, was the first conspicuous example of a large ship driven by Diesel engines. Her economy of fuel at once commanded attention. She was naturally hailed with delight by the powerful oil interests whose position, already strong in the mercantile marine through the extended use of oil under boilers, would become impregnable if the Diesel engine were generally adopted. In some important quarters the Diesel engine became the vogue. During the post-War years of marine reconstruction the number of oil-driven motor-ships rapidly increased, and it is still increasing. Of merchant vessels launched during the year 1930, considerably more than half the tonnage was motor-driven. At this rate, a superficial observer might fancy that steam was in process of being driven off the high seas. But if that were his conclusion I think he would be quite wrong.

None of the greatest and fastest ships is motor-driven—neither the *Leviathan,* which at present heads the list, nor any of the other leviathans of the deep, with their tonnages of 40,000 or 50,000 tons or more, and their speeds ranging from 20 to 28 knots. This is true not only of the older ships but also of the newest, such as the *Europa* and the *Bremen* and the *Empress of Britain,* and the giant Cunarder which is now on the stocks and is confidently expected to surpass them all. For such vessels, motors do not give the concentration of power that is needed, whereas turbines do give it, and give it easily.

When we turn to vessels of intermediate types, we find the liveliest contest between the steam turbine and the Diesel motor. Some nations, such as Denmark, Norway, and Sweden, conspicuously favour motors. Others, such as America, no less conspicuously favour steam. One feels that both cannot be right. Nor can British practice, which is much divided, be right either. The choice would sometimes seem to depend more upon the taste and fancy of a dominating personality than upon a careful weighing of arguments such as appeal to engineers. One finds some shipowning companies going strongly for Diesel engines and other companies going no less strongly for steam. A notable example in the steam group is the Canadian Pacific Company, the superintending engineer of which, Mr. J. Johnson, has communicated to the Institution of Naval Architects a very full statement of the grounds which have governed that company's engine policy. His paper deserves careful study; I have not been able to find any equally detailed and convincing statement on the other side.

When we attempt to appraise the merits of the rivals and to estimate their chances in the more distant future, we see that from the thermodynamic point of view the Diesel engine still has a small advantage. On the other hand, its oil is more costly than fuel oil for boilers; it must have lubricating oil, too, and the first cost of the engine is substantially greater than that of steam plant. In respect of weight and of space occupied there is not much to choose. As to durability, I cannot speak; so far as I know, there is still a dearth of published facts about the cost of upkeep with Diesel engines. *Prima facie,* the great number of reciprocating parts is a serious drawback. There must be a great number because the safe limit of cylinder size is soon reached, and it is only by having many cylinders that any large aggregate of power is developed. In a recent Diesel-engined liner of the luxurious type, 12 Diesel cylinders operate on each of four shafts, making 48 in all, to produce a speed of 18-20 knots. Besides these 48 main cylinders, there are 24 more which serve purposes that are auxiliary but essential to the working of the main engines. Consider the number of working joints, of valves, of valve-rods and tappets, besides pistons and connecting-rods, which this involves. Does such an accumulation of reciprocating pieces with their hammer-blow accelerations mark a real engineering advance as compared with the cosy hum of a turbine engine-room, and has it come to stay? Frankly, I think not.

Now, a final question. Can anything be done to re-establish the ancient connexion of the merchant service with the British coalfields? Remember that here, and in most other places, the cost of coal is substantially less than that of oil for the same quantity of heat. Where oil scores is in its greater convenience of handling. Much has been said and written about restoring prosperity to the miners by converting coal into oil. As a chemical operation it is quite possible to make oil from coal; as a commercial proposition it is impracticable, so long as Nature continues to supply oil directly from the bountiful stores on which man now draws with prodigal ease. Ships that burn oil must have it come to them from sources outside Great Britain. Can we expect ships to return to the use of coal as fuel? For some classes of ships I think we may, though not all classes. Neither in the navy nor in what one may call the upper division of the mercantile marine—the luxurious express liners which carry fastidious passengers and must keep to a time-table that means quick fuelling—can one expect a reversion to coal so long as oil fuel can be got at anything like its present price. But with cargo-liners and big cargo-boats the case is different. I think those engineers are right who contend that for such ships a highly economic mode of working would be to use pulverised coal for steam-raising in a small number of large boilers of the water-tube type, with a pressure of, say, 500 lb. and a temperature of 750° F., each boiler having its own pulverising mill and being fitted also for burning oil as an alternative fuel. In such a scheme there would be no untried elements, but the combination of the elements would be experimental, and a conclusive demonstration of its advantages can be obtained only by testing it out on a large scale in sea-going ships.

In taking leave of our prophet of 1881, if we were to catch from him the mantle of prophecy we should wear it ruefully; we should all be Cassandras or Jeremiahs, obsessed with the cheerlessness of the industrial outlook, and finding no escape from the conviction that the easy supremacy of Britain, as Bramwell knew it, can never be recalled. But my last word must not be an unqualified Ichabod. The engineers of to-day have as much courage and enterprise as their fathers, and they have an infinitely better understanding of the scientific principles on which, as on a smooth highway, the advance of engineering must steadily proceed. Moreover, to recognise evils, and the causes of evils, may be the first step towards their cure. The world has learnt, through a sharp lesson, that the gifts of the engineer are good gifts only if they are wisely used; that the new powers he has evoked have brought new dangers against which mankind must resolutely guard if it is to save its soul alive. The malignity of individuals and the madness of nations now command forces of destruction such as more primitive communities never knew, and were happier not to know; and apart from clamant and appalling abuses of gifts which ought to be beneficent, we have become aware of a more subtle and perhaps graver social menace. We see the mechanised arts of production overreaching themselves, supplying commodities in a volume which cannot be absorbed, and with a facility that tends to deprive man of his richest blessing to body and spirit—the necessity of toil.

But these thoughts take us too far afield. They point to problems now conspicuously urgent, which, for the salvation of society, the engineer, the economist, and the moralist must jointly set themselves to solve.

The British Association Centenary.

Commemorative Service at Liverpool Cathedral.

The Dean and Chapter of Liverpool lose no occasion to make their great Cathedral the scene of public commemoration, and the centenary meeting of the British Association for the Advancement of Science was celebrated there with a ceremony on Sunday, Sept. 20, which will remain vivid in the minds of everyone who assisted in it. It happens that this year's Lord Mayor of Liverpool, Alderman Edwin Thompson, was one of the Association's local secretaries for the meeting in Liverpool in 1923, and is the son of a local secretary of the meeting of 1896. He was therefore able in a special sense to express the feelings of Liverpool people on this occasion; he entertained the president and president-elect of the Association at the Town Hall, and conducted them in full state to the Cathedral, where representatives of the University of Liverpool, the medical profession, and other public bodies, in academical robes, made a bright mass of colour in the choir, and the nave was filled to the doors; indeed, the greater part of the service had to be repeated later in the day. The thanksgiving service fell into three parts. The Dean, with the two presidents, and other members of the Association, presented themselves before the Bishop at the junction of choir and nave, and the president-elect, General the Rt. Hon. J. C. Smuts, addressed him in the following words:

Sir,—Bid a Blessing on this congregation assembled to render thanks for the increase of knowledge by the devoted labours of men and women in many lands, and more especially for the British Association for the Advancement of Science. This body was established a hundred years ago to give more systematic direction to scientific inquiry, to promote intercourse between those who cultivate science in different parts of the British Empire with one another and with philosophers of other countries, to direct the general attention to the objects of science, and to remove disadvantages of a public kind which impede its progress. The Spirit of God has used it to interpret the process of Nature and the doings of man, and by unrestricted interchange of observations, projects, and beliefs, the outlook of the nations on the world in which they live has been transformed. Vain fears and anxieties have been assuaged by clear thinking and wise endeavour. The real dangers and perplexities of our daily lives have been relieved by forethought and mutual help. The amazing structure and intricate processes of the universe have been set forth for reverent and devoted contemplation by students young and old, of all sorts and conditions. In these several ways human sympathy has been widened in the common task of mutual enlightenment and public service, men's minds have been awakened to the revelation of that which works in all and through all, and their grasp has been strengthened on the principles and the meaning of life.

The Bishop replied to General Smuts in historic words, as follows:

May God, the Fountain of all knowledge, fill you, who have gathered in this house for commemoration, with understanding and joy. May He keep you steadfast and persevering in your search for truth. And may the blessing of the Lord come upon you abundantly.

O Thou, who in every generation hast moved Thy chosen servants to seek Thy truth: continue we beseech Thee, so to inspire us in this age that, searching the works of Thy hands, we may find Thee in all that Thou hast made, and finally may know Thee perfectly revealed in the Spirit of thy Son, Jesus Christ our Lord.

A lesson was read from Ecclesiasticus xliv., by the president, Prof. F. O. Bower, "Let us now praise famous men, and our fathers that begat us", and an anthem was then sung:

Lord, who hast made us for Thine own, hear as we
sing before Thy throne.
Alleluia, Alleluia.
Accept Thy children's, rev'rent praise for all Thy
wondrous works and ways.
Waves, rolling in on ev'ry shore, pause at His footfall
and adore,
Ye torrents rushing from the hills, bless Him whose
hand your fountain fills.
Earth, ever through the power divine, seedtime and
harvest shall be Thine.
Sweet flowers that perfume all the air, thank Him
that He hath made you fair.
Burn, lamps of night, with constant flame, shine to
the honour of His name.
Thou sun, whom all the lands obey, renew His praise
from day to day.
Alleluia, Alleluia.

The commemoration was delivered, in the form of a bidding prayer, by Prof. J. L. Myres, one of the general secretaries of the British Association, and formerly Gladstone professor of Greek and lecturer in ancient geography in the University of Liverpool. After each prayer the response of the Dean was "Bless ye the Lord", and of the congregation "Praise him and magnify him for ever".

Ye shall remember those who in all times and in all places have devoted their gifts of intellect and imagination to interpret the laws of thought, the place of man in the universe, and the nature of reality;

Such as were Aristotle, Da Vinci, Bacon, Descartes, and Kant.

Ye shall remember all who have explored the properties of numbers, and the mysteries of time and space;

Such as were Pythagoras, Archimedes, Newton, Leibniz, Gauss, and Poincaré.

Ye shall remember all who have determined the courses of the stars, the place among them of sun, moon, and this earth of ours, and have given to all those, whose business is in the great deep, sure guidance to the haven where they would be;

Such as were Ptolemy, Copernicus, Kepler, Tycho Brahe, Halley, Herschel, and Huggins.

Ye shall remember all whose profound vision and infinite patience have revealed the ever-changing uniformities of the great forces of Nature; and made light and sound, heat and cold, lightning, wind, and flood subservient to the purposes of man;

Such as were Galileo, Gilbert, Watt, Faraday, Joule, Clerk Maxwell, Rayleigh, Hertz, and Parsons.

Ye shall remember all who have distinguished the natural elements, verified their properties and affinities, and thereby compounded substances unknown before, serviceable to health and in the arts;

Such as were Paracelsus, Boyle, Dalton, Priestley, Lavoisier, Davy, Berzelius, and Mendeleeff.

Ye shall remember all to whose vision across the ages the mountains and the seas are but of yesterday; who have laid bare the foundations of the world, and revealed its hidden treasures surely and safely for our uses;

Such as were Hutton, Nicolaus Steno, William Smith, Lyell, Bouchier de Perthes, and Suess.

Ye shall remember all who, not sparing life or fortune, set forth to find and win new homes for the multitude of our folk, to build the waste places of the earth, so that the desert should rejoice and blossom, and the men who stood far off might see a great light; for all travellers and explorers, and for those who were moved by great thought to send them forth, and to set down and make known their discoveries;

Such as were Marco Polo, Prince Henry the Navigator, Christopher Columbus, Banks, Cook, Humboldt, Franklin, Livingstone, Nansen, and Scott.

Ye shall remember all who have set in order the lineage of all living things, animals and plants, observed their habits and haunts, their struggles and survivals through the long lapse of time, the wonderful variety, infinite beauty, and subtle adaption of each to its proper life; their coming to birth and passing away: who have distinguished among them the friends and the foes of man, and sought to diversify by human skill the manifold works of creation;

Such as were Hippocrates, Galen, Linnæus, Cuvier, Lamarck, Darwin, Hooker, Huxley, and Mendel.

Ye shall remember all who have applied the principles of the several sciences to the tillage of the soil, the avoidance of famine and pestilence, the breeding and sustenance of flocks and herds, and the abundant provision of our daily bread;

Such as were Jethro Tull, Daubeny, Liebig, Lawes, and Theiler.

Ye shall remember all who, by their intimate study of the functions of life, have made plain the mysteries of many diseases and abated their ravages; and brought knowledge of our bodily frame to the better study of the mind in sickness and in health;

Such as were Vesalius, Harvey, Hunter, Claude Bernard, Johannes Muller, Pasteur, and Helmholtz.

Ye shall remember all whose contemplation of the divers races of mankind, the manner of their lives, the ordering of their societies, their customs and beliefs, and their manifold dealings each with his neighbour, for the enjoyment of Nature's gifts and the fruits of reason and toil, to the increase of the wealth of nations, have contributed to mutual understanding among the peoples and peace on earth among men of good will;

Such as were Bodin, Locke, Montesquieu, Adam Smith, Quetelet, Galton, and Tylor.

Ye shall remember all by whose precept and example, schools, colleges, and universities have been founded, so that true religion and sound learning may ever flourish and abound; for all teachers of those who learn; for all guides and masters of those who teach;

Such as were Socrates, Plato, Herbart, and in our own land William of Wykeham, Colet, and Arnold, Thring, Sanderson, and all founders and benefactors of the University of Liverpool.

The Bishop, at the end, taking up the same theme in more general terms, said:

And lastly, let us remember all who in the wise use of their abundance or their power, by their gifts of tongue and pen, by their particular skill, industry, and patience, have contributed to the advancement of learning, the application of science to the common good, or to the spread of the new light of reason among dark places and cruel habitations. Line upon line, precept upon precept, here a little and there a little, the works of each proclaim the Spirit of Him who wrought in them.

Then, after a hymn, the sermon was preached by the Bishop of Birmingham, Dr. E. W. Barnes, on the words, "The things that are not seen are eternal".

Finally, after hymn and anthem, the congrega- was dismissed with blessing by the Bishop.

In the evening a more informal gathering, such as is customary in Liverpool Cathedral, was conducted by the Chancellor of the Diocese, and addressed by General Smuts and Sir Oliver Lodge. The Cathedral was full, and an even larger number was turned away.

SECTIONAL MEETINGS AND DISCUSSIONS.

The meetings of the British Association have become part of our intellectual life as a nation and as an Empire. The general public awaits with an eager interest the messages of our leaders of thought about the actual trend of civilisation, while research students expect to find in their pondered pronouncements an indication of the landmarks in the unknown reached by science, and inspiring examples and methods for its own studies. The meeting of the British Association this year had, however, a wider interest, owing to the centenary celebrations of its foundation. When one looks back on the work of the Association during these hundred years from its first meeting organised at York by

Brewster and a band of enthusiastic men of science, one can only recognise the immense services it has rendered to science and the growing importance of its work.

The opening address of General the Right Hon. J. C. Smuts and summaries of the addresses of the presidents of sections have already appeared in Nature of Sept. 26. Taken together, they represent a broad survey of what science has done in recent years and what is to be expected of it in the near future. The problems of the constitution of matter, of the origin of life, of the various aspects of physiology, and of the increase and applications of mechanical power have been restated and broadly illustrated, while the papers read at the sectional meetings have considered special points of particular interest in the various branches of knowledge, from asymptotic partition formulæ to London tunnelling problems, the psychology of facial expression, or the early bronze age site in western Macedonia.

Questions dealing with integral calculus, higher pure geometry, and the application of mathematics to such problems as the relativistic wave equation, viscosity, and molecular physics seem to have been prominent among the mathematicians; while questions referring to the invention and use of powerful optical instruments and to the study of atmospheric conditions have been dealt with in the department of cosmical physics. The outstanding discussion in the department of Section A was one on the evolution of the universe, opened by Sir James Jeans at a crowded assembly in the Central Hall, Westminster. We propose to publish in a later issue the contributions to this discussion. In the Chemistry Section, much interest was shown in the study of the properties of electrolytes in various conditions, and also in the constitution and biological effects of vitamins, as well as in molecular and atomic structures. A fine collection of exhibits of various chemical compounds added to the practical value of this important section.

Geologists were interested to hear of the unknown prehistoric conditions of the London district. But the conflicting views of Sir Arthur Keith, Prof. H. L. Hawkins, Prof. H. F. Osborn, Prof. Swinnerton, Prof. A. E. Trueman, Prof. D. M. S. Watson, and Dr. W. D. Lang on the evidence of palæontology with regard to evolution could scarcely serve as a safe guide to the layman in one of the fundamental questions affecting the human race. Geological problems, however, are closely connected with geography; so that the transition between these two sciences appears to be easy and natural. The retrospect of geography at the British Association, sketched out by Dr. H. R. Mill, was a useful introduction. Yet the trend of the discussions has shown that physical geography rather than descriptive geography has the favour of the man of science. Perhaps we know already too much about what we have on our planet: what we want to know is how all this came about, or, to put it in technical terms, what are the origin and nature of the earth's crust.

As would be expected, zoology was dominated by inquiries on evolution, natural selection, genetics, and Mendelism, applied to the whole range of living organisms; while physiology dealt with the advanced aspects of the subject, especially with reference to human beings. A most interesting discussion in this connexion was that on problems of resuscitation from asphyxia, electrocution, drowning, etc., when the learned diagnoses of Sir Bernard Spilsbury, Prof. Y. Henderson, Prof. J. S. Haldane, Sir Francis Shipway, and other experts were given. Mechanical causes, inhalation of air deprived of oxygen, paralysis of the respiratory centres were considered under their various aspects as the chief causes producing asphyxia, and methods of resuscitation were suggested. Going further into the problems of the human complex, psychologists discussed the diverse questions pertaining to child psychology, analytical and abnormal psychology, and the experimental side of their inquiries. The delicate subject of mental deficiency and the psychology of the senses were also among the items considered. On the other hand, the ancient history of man was presented in a series of technical papers in the section of anthropology, in which primitive races and prehistoric man were studied side by side. Among the archæological theories put forth in this section, Dr. R. E. Mortimer Wheeler's paper on the excavations of Verulamium (St. Albans) was of a special interest.

Botany and agriculture received also full consideration. Plant morphology and plant diseases, especially the questions connected with wood preservation in forestry, were carefully analysed. At the same time the practical value of botany was the subject of a symposium on the training of botanists for economic and industrial positions, in which Sir Arthur Hill, Sir John B. Farmer, Prof. V. H. Blackman, Dr. W. B. Brierley, and Mr. J. Ramsbottom took part. Problems referring to agriculture proper were dealt with in a variety of papers which should prove of immense value to the practical side of farming, cattle breeding, and the allied arts of the countryside. The economic questions relating to agriculture in the British Empire were also discussed generally.

Economic science had naturally an important part to play in the meeting, and the sections devoted to economics and statistics, with the connected subjects of industry and engineering, scored high in the proceedings with some brilliant papers by experts and leaders of industry. A cursory remark may also be made about the section of education, in which the suggested establishment of a central institute for imperial education was thoroughly discussed.

On the whole, the addresses and papers read at the centenary meeting of the British Association show conclusively that if the scientific worker knows more and more about Nature, he is less and less inclined to present any clear-cut or definitive solutions to the major problems he sets forth to answer. A quarter of a century ago, the positivistic and materialistic conception of science allowed him a greater pride, almost a sense of infallibility, about his conclusions. Now, however, the very magnitude of his knowledge compels him to greater modesty. Perhaps that is the proper attitude he should adopt; if one admits that the final light that man seeks in this world should come from other sources which, though different from those of science, tend, however, to mould the human mind and its aspirations into a nobler and finer unity.

The freedom of the City of York was conferred on General Smuts when an invited party visited the city on Sept. 26.

At a reception given by the University of London on Sept. 28, the vice-chancellor delivered an address of welcome to the delegates to the centenary meeting, and then, by desire of the Senate, conferred the honorary degree of doctor of science, *Honoris Causa*, on the following:

General the Rt. Hon. Jan Christiaan Smuts, C.H., F.R.S.;
Prof. Sir Frederick Gowland Hopkins, P.R.S.;
Sir Joseph John Thomson, O.M., F.R.S.;
Sir Charles Scott Sherrington, O.M., G.B.E., F.R.S.;
The Rt. Hon. Lord Rutherford of Nelson, O.M., F.R.S.

OFFICERS AND COUNCIL.

Sir Alfred Ewing, lately principal and vice-chancellor of the University of Edinburgh, has been elected by the General Committee president of the Association for next year, when the meeting will be held at York. Hitherto the president has assumed office at the inaugural meeting of the Association and has then given his presidential address. By an alteration of one of the Statutes, recommended by the Council and adopted by the General Committee, the president will in future assume office on Jan. 1, will deliver his address at the annual meeting held during his year of office, and will retire at the end of the year. The advantages of these changes are stated by the Council as follows:

(1) The president will be responsible administratively for the major part of the preparation of arrangements for the annual meeting over which he is elected to preside, and his influence can be more directly brought to bear upon them.

(2) In particular, he will take the chair at the joint meeting of Organising Sectional Committees in the January preceding the annual meeting, which has now become a regular and principal part of the mechanism of preparing the programme.

(3) As a point of minor but still recognisable importance, he will arrive at the place of the annual meeting as president, not as president-elect, and possible confusion in the local public mind will be avoided.

(4) After the annual meeting he will still be in office to preside over those meetings of the Council at which matters arising out of the annual meeting are principally dealt with.

The new members of Council are Dr. J. Drever, Prof. T. E. Gregory, Prof. H. S. Hele-Shaw, Prof. E. B. Poulton, and Prof. A. M. Tyndall. Considerations of health would not permit Prof. F. J. M. Stratton to take full part in the preparations for the centenary meeting; and he cannot be present at next year's meeting. Prof. P. G. H. Boswell was therefore appointed as an additional general secretary. Prof. J. L. Myres, who has been one of the general secretaries of the Association since 1919, has intimated that he will not seek re-election after next year.

Obituary.

PROF. A. S. PRINGLE-PATTISON.

BY the death of Prof. Andrew Seth Pringle-Pattison on Sept. 1, at the age of seventy-five years, philosophy lost one of the outstanding figures in a period of remarkable activity in that department. He was one of the first to see the significance for English thought of the impulse that came from the sympathetic study of Kant and Hegel in the 'sixties and 'seventies of last century. With the late Lord Haldane he organised the epoch-making manifesto contained in "Essays in Philosophical Criticism" which appeared in 1883 and included contributions from others who afterwards became famous in their several lines of research, J. S. Haldane, Bernard Bosanquet, W. R. Sorley, W. P. Ker, Sir Henry Jones, and James Bonar.

More cautious and more determined to make sure that no vital element in experience was being sacrificed to a first enthusiasm than some of his more ardent colleagues, Pringle-Pattison came forward in the next period of his philosophical development as a trenchant critic of what he held to be sinister features of the new movement. The doubts expressed in "Hegelianism and Personality" in 1887 seemed to be confirmed by the publication of Bradley's "Appearance and Reality" in 1893, and his essay in criticism of this work in "Man's Place in the Cosmos" seemed to separate him more widely still from his former idealistic associates. But the apparent recoil was only the preliminary to a more confident advance to the more personalistic form of that doctrine that found full expression in his Gifford Lectures in 1912–13 on "The Idea of God in the Light of Recent Philosophy" and has since had a growing influence both in England and America.

The general line of Pringle-Pattison's thought is indicated in the phrase which, so far as I know, he was the first to use of philosophy as "Criticism of Categories". The category prominent in nineteenth century thought was that of mechanical causation—the attempt to resolve everything into elements with which, as *effect*, it could be equated. This he held to be applicable (and possibly adequate) in certain limited spheres of phenomena, as in mechanics. But as we pass to other orders of fact, as to that of life, no preceding set of facts can account for their combination in a phenomenon essentially different from them. Here on the contrary "the true nature of the cause only becomes apparent in the effect". Equally certain was the insufficiency of any merely biological interpretation of the world of moral and religious experience. It is impossible to do justice to the sense of obligation and the instinctive admiration of unselfish devotion to far-reaching ends such as truth, beauty and moral perfection on any theory which takes the survival and material well-being of the species as the supreme goal and all else as instrumental to them—incidental results and by-products of the cosmic system. All explanation in a word of the higher by the lower is philosophically a *hysteron proteron.* Everything remains unintelligible until we invert the order of naturalistic explanation and go to work on the supposition that a purposeful moral intelligence is in reality the key to the world's meaning, the fact in the light of which all other phenomena must be read. In his own words, "every true philosophy is an attempted theodicy"—the vindication of a divine purpose in things.

However extravagant this claim may seem to those wedded to another order of thought, its vindication has been the dream of a long line of great thinkers since the time of Plato who found alone in the Good the adequate principle at once of the being of things and of our understanding of them. Pringle-Pattison's interpretation and defence of this thesis against prevalent forms of naturalism on one hand and forms of idealism, which sought for the principle of reality in a sphere beyond Good and Evil, on the other, ranks him with the great teachers, including Sir William Hamilton, who preceded him in the chair he so long occupied in Edinburgh.

An account of Pringle-Pattison's opinions gives, however, an imperfect idea of his work as a writer. It was the way in which he developed them out of a singular fullness of knowledge of contemporary philosophy, and the command of a peculiarly graceful style derived from an equally wide knowledge of the best in literature, that gave that work its peculiar distinction. Added to this he was known to his friends and his fellow-townsmen as a man of singular gentleness of manner and dignity of presence. He lived and looked the philosopher. Yet when called upon by the inheritance of an estate in the country to play the part of a Scottish laird, he surprised his friends by the firmness and efficiency of his management. Without the interest of his brother and colleague Prof. James Seth in the practical life of his city, and contrasting with 'Prof. Jim' in the more formal method of his teaching from written lectures, these self-limitations enabled him to give a certain completeness to the literary expression of his ideas in a long series of works of uniform distinction, closed only last year by the publication of his "Studies in the Philosophy of Religion", described by the *Times* of Sept. 2 as "among the best in the apologetics of rational theism".

Pringle-Pattison was LL.D. in his own university, honorary D.C.L. of Oxford, and a fellow of the British Academy. Among his early friends, besides those already mentioned, were Ambassador J. G. Schurman and the late Lord Balfour, who founded the lectureship under that name in the University of Edinburgh with the express purpose that Andrew Seth, as we then knew him, should be the first to hold it. Seldom have youthful appointments been better justified.

J. H. Muirhead.

We regret to announce the following deaths:

Sir Gregory Foster, Bart., formerly provost of University College and vice-chancellor of the University of London, author of many educational works, on Sept. 24, aged sixty-five years.

Dr. Charles A. Keane, formerly principal of the Sir John Cass Technical Institute, Aldgate, on Sept. 18, aged sixty-seven years.

News and Views.

As we go to press, we have received the following radiogram, dated Sept. 28, from Sir C. V. Raman, F.R.S., and S. Bhagavantam: "Experimental demonstration of spin of light.—The depolarisation of Rayleigh scattering of monochromatic light in carbon dioxide gas does not diminish to one quarter of its value when spectroscopically separated from rotational scattering, as demanded by existing theories of radiation. The actual observed diminution, from 10 per cent to 6 per cent, is quantitatively explicable, assuming that common light consists of spinning quanta possessing one Planck unit of angular momentum.—C. V. Raman and S. Bhagavantam."

This is the centenary of the discovery of miners' safety fuse—more generally known as Bickford fuse—by William Bickford. He was a Devonshire man, but having married a Cornishwoman, he went to live in the little village of Tuckingmill in the mining area of Cornwall, and there he first started his experiments on safety fuse. In this he was actuated by humanitarian motives, for he had nothing whatever to do with mining, his business being that of a currier. Blasting operations as conducted one hundred years ago were exceedingly difficult and dangerous. The only explosive then known was gunpowder, and though the handling did not involve any great risk, the methods in use for conveying the fire to the charge were definitely dangerous. It was at this stage that accidents were of such frequent occurrence, and the old records in Cornwall and elsewhere show that the fatalities were very great. But it was the number of permanently maimed men utterly incapacitated for work through the loss of fingers, an arm, or a leg, visible evidence of the hazardous nature of mining, which spurred Bickford on with his work. The most effective and possibly the safest device employed in Cornwall for conveying the fire to the charge was to fill goose quills with crushed gunpowder, after nipping off the thin ends. Thus a thin end of one quill was fitted into the wide end of another, and by this means, a column of powder was built up which, though fragile, was fairly effective but very uncertain. This in turn was set off by touch-paper.

BICKFORD had naturally many disappointments and failures when carrying out his experiments, and indeed was just on the point of abandoning the whole thing when in visiting a friend in his rope-walk he had the idea that the fibre of the rope might be so spun as to enclose a core of powder fed from a funnel. He achieved success in the end mainly with the assistance of a mechanical genius called Davey, who must share the credit. Application was in due course made for a patent, and the specification, which is dated Sept. 6, 1831, reads as if it had been drafted yesterday, so minutely and correctly are the operations described. Unfortunately, Bickford did not long survive his invention, but his family carried on the work. The little workshop where the first manufacturing operations were carried out still exists, but around it has grown a fine up-to-date works. Through the safety lamp invented by Sir Humphry Davy, one of the two great causes of accidents in mining was removed, and through Bickford fuse the other was, after a time, definitely eliminated. These two inventions have probably done as much as any other to conserve human life. Bickford reaped no financial reward from his invention, and it was only after many years that the fuse was known outside of Cornwall. Nevertheless, his name is worthy of a passing thought even in these crowded days.

THE discussion on human population which was held in Section D of the British Association on Sept. 26 is of peculiar interest in view of the general theme of Prof. E. Cannan's presidential address to Section F. Prof. Cannan's argument is that the population of the world is almost stationary. He, like Prof. J. S. Huxley in the discussion, points out that migration is rapidly coming to an end. With contraception affecting all countries a new problem is arising—that of either over- or under-population. Prof. Huxley also emphasised the effect of progress in medicine, sanitation, and so forth in lessening the rigour of natural selection. The fertility and possible sterilisation of individuals is also receiving much attention now, thus placing the problem of population on biological bases. Prof. A. M. Carr-Saunders considers that there is not so much cause for concern over the decline in birth-rate as there is in the connexion between this decline and western civilisation and culture. Prof. L. T. Hogben made a plea for more intensive physiological research into human reproduction. The recent decline in the European birth-rate is undoubtedly due to limitation of parenthood owing to the spread of contraceptive measures, but Prof. Hogben is not prepared to place all the responsibility on contraception.

PROF. E. W. MACBRIDE considers that, now the problem of over-population cannot be settled so easily by migration to unoccupied territories, one of two things is possible: either war or internal degeneration. Prof. F. A. E. Crew looks upon the problem from the point of view of the geneticist. He emphasised the inability of pure-bred British stocks to claim biological harmony with habitats outside the temperate zones. If, therefore, parts of Australia cannot be colonised by the Australians, but can be by Italians, Japanese, or Chinese, then the latter have the prior right. Similarly have the Indians preferential claim for the greater part of East and South Africa. Nevertheless, being of such mixed racial composition ourselves, it might be possible finally to suit the whole Empire by a better distribution of our migrants among its diverse parts. In this connexion it is interesting to note Prof. Cannan's conclusion, that the remedy for unemployment is mobility in regard to both place and occupation.

A GROUP of biologists of the University of Minnesota has filed a memorandum with the White House Conference on Child Health and Welfare, suggesting that a special conference of experts on heredity be called, to see what can be agreed upon as a positive programme looking to the application of knowledge of heredity to the human species, and to recommend how such a programme should be carried out. In this connexion, Dr. E. P. Lyon, dean of the Medical School, University of Minnesota, has issued through Science Service, Washington, D.C., a statement in which he points out that man has enormously improved domestic animals by the intelligent application of the laws of heredity, and should be able to apply the same intelligence to similar ends in regard to his own species. Human rights are involved, but the right of every individual to have children is opposed by the right of the hopelessly diseased baby to remain unborn. It is not necessary to have any model towards which to aim, but progress can begin with elimination of the manifestly unfit by breeding only from the fit. He suggests that public opinion should be educated on this matter, and that a programme might be adopted extending over one hundred years. This would be further ahead than the human race has ever planned before. At present, very large expenditure and enormous social effort are directed to the environmental side, while the practical aspects of heredity as applied to man are comparatively neglected.

THE twelfth Annual Report of the Ministry of Health, which relates to the year ended on March 31, 1931, has recently been issued. (London: H.M. Stationery Office. 5*s*. net.) The subjects dealt with fall under the main heads of public health, local government and local finance, poor law, national health insurance, and contributory pensions, the Annual Report of the Chief Medical Officer of the Ministry being published separately. During 1930, 136,515 samples of food and drugs were analysed, of which 6496 were reported against, a percentage of 4·8, which is the lowest recorded. A notable feature of the year was the considerable decline in the number of notified cases of, and in the deaths from, pneumonia; there has also been a steady decline in the number of cases of encephalitis lethargica, but the prevalence of mild smallpox continues. With regard to housing, the average cost of non-parlour houses, £344, is only £18 less than that in 1928, and dissatisfaction is expressed that there should not have been a more substantial reduction. Attention is directed to the serious lack of reliable information regarding the flows of rivers and streams, and a sub-committee of the Advisory Committee on Water has been appointed to consider what measures can be taken for the accurate gauging of rivers and underground water.

THE activities of local authorities in Great Britain in the sewering of their areas have, according to the Annual Report of the Ministry of Health, been more than maintained during the year, and loans sanctioned for this purpose amounted to nearly nine million pounds, and the total sum for this purpose since the War is approximately fifty-two million pounds. The report by Mr. Owen Llewellyn, inspector under the Canal Boats Acts, is of the nature of a retrospect, for he is retiring after thirty-two years' service. He remarks that during his period of office many hundreds of miles of canals have become derelict or have fallen into disuse. Motor-engined boats are taking the place of steamers and of horse-drawn boats, though the last-named are the most economical form of transport in many, especially hilly, districts. On canals as a whole, there seems to be no decrease in the number of children found on boats, and the 'floating school' at West Drayton for canal-boat children has proved a success. It is impossible to state with any certainty how many boats exist and are at work, for there is no legal obligation to report the end of once-registered boats. The last portion of the volume contains the report of the Welsh Board of Health, with a number of appendices.

IN his evening discourse to members of the British Association on Sept. 24, entitled "Zoos and National Parks", Sir Peter Chalmers Mitchell described the problems of and need for three types of animal reserves—zoological gardens, zoological parks, and national parks. There are many popular ideas of how various animals should be kept; but Sir Peter pointed out some of the difficulties of keeping animals under conditions resembling so far as is possible their natural habitat. Such problems are not relieved by the diverse nature of the different species of animals seen at our great zoological gardens. Experience in the keeping of animals under such conditions brings out some surprising facts. Examples are the necessity for sunlight and a suitable temperature. Nearly all animals love sunlight, even polar bears and owls; given the chance, they bask in the sun and benefit from it. A constant temperature is not desirable for any kind of animal; variations should be made for the well-being of all animal types. Another great asset, to nearly all animals, is plenty of opportunity to obtain fresh, open air.

ONE point especially emphasised by Sir Peter is the fact that the zoological garden should not be looked upon merely as an adjunct to the amusement and general instruction of the public, but should be regarded as a splendid field for research. Much more should be done in this respect. An example of this is the behaviour of the kangaroo when under an anæsthetic. The kangaroo is never known to utter any kind of sound normally, yet when subjected to an anæsthetic, probably partly through fright and partly due to the anæsthetic, the animal utters a cry similar to that of the marsupial wolf. Here is an opportunity for research into the cries of animals under various conditions. Many other such problems are still awaiting investigation, which can be carried out advantageously only in a zoological garden. Zoological parks present a still further difficulty in that they allow much more freedom, and therefore only animals with a considerable range of adaptability can be chosen. National parks are useful for the preservation of types of fauna in danger of extinction, the American bison being now a historical example. The chief agent in animal extermination is the advance of civilisation and not sportsmen or scientific collectors.

THE Trustees of the British Museum celebrated on Sept. 29 the fiftieth anniversary of the opening of the Natural History Museum building at South Kensington. The exact date of the opening was April 18, 1881, but the celebration was deferred so as to come within the period of the centenary meeting of the British Association. About a hundred and fifty delegates of museums and learned societies at home and abroad were received by the Trustees at the afternoon meeting. The Earl of Crawford and Balcarres, chairman of the Jubilee Celebration Sub-Committee of the Trustees, presided, and was accompanied on the platform by Lord Rothschild, Sir David Prain, Mr. F. Cavendish-Bentinck, and other Trustees, as well as by the director of the Museum, Dr. C. Tate Regan. Lord Crawford, in opening the proceedings, welcomed the delegates and expressed the pleasure which the Trustees felt that so many had been able to attend the celebration in spite of the world-wide financial difficulties which were then prevailing. Dr. Regan then gave a brief account of the history of the Museum and of the development of the collections contained in it. The delegates were then individually received by the Trustees. In the evening, the Government gave a reception at the Museum, which was attended by the delegates, as well as by a large number of naturalists and other scientific workers attending the meeting of the British Association. The guests were received by the Prime Minister, Rt. Hon. J. Ramsay MacDonald, M.P., and Miss Ishbel MacDonald.

A RECENT writer in the American journal *Forest and Stream* gives an account of a lion farm at El Monte, U.S.A., the property of Mr. and Mrs. Gay. As an adult lion is worth a thousand dollars even untrained, the domestication of the lion—long known as the readiest of sensational 'wild beasts' to breed in captivity—is evidently a paying proposition; and, apropos of this, it may be as well here to give a tentative list of the known domestic mammals, as no such list, embodying all the latest results, appears to exist. The only other feline domesticated is the common cat; of the dogs, we have now, besides the ordinary dog, the common and arctic foxes; of the weasels, the ferret, mink, and skunk. The domestic rodents comprise the rabbit, guinea-pig, rat (*Mus decumanus*, not *rattus*), mouse, and musk-rat, probably also the coypu and the Patagonian cavy (*Dolichotis patagonica*). Of ungulates, nearly all the known species of *Bos* have been domesticated—the common ox, zebu (if this be really distinct), water-buffalo, yak, gaur (the domestic form being known as gayal or mithan), and banteng, while the two bisons are at any rate emparked; other domesticated hollow-horned ruminants are the sheep and goat and probably the Barbary sheep (*Ammotragus lervia*) and blackbuck (*Antilope cervicapra*), and in East Africa, at any rate, the eland. Among the deer, the milou (*Cervus davidianus*) has never been known except as a park animal; while the reindeer and fallow deer are well known as domestic, and there are park races of the red deer and doubtless others. The two camels (only known certainly as domestic), the llama (the domestic descendant of the guanaco), the pig, the horse, the ass, and Bennett's wallaby, a well-established park animal, complete the list, in which it is to be noted that among the recent achievements in domestication only that of the eland has practical utility as its object.

MR. DENIS BUTLER, of Goodhart Way, West Wickham, Kent, has sent an account of curious behaviour in a North American corn-snake (*Coluber guttatus*) in reference to moles. The snake, which had been kept in an open-air cage, escaped, and on recapture, after about a week, showed by a bulge in the stomach-region that it had fed well. When the cage was next visited, three decomposing moles were found there, which the snake had eaten while at large; most of the flesh seemed to have been digested, but the skins and bones were intact. After about a week, the body of a fourth mole, which must have burrowed in and been swallowed, was found in the cage. It is suggested that this apparent inability to digest moles, when other animals, such as mice, are digested bones and all, is strange; but in the case of the first three found the disturbance of the snake's system caused by recapture no doubt caused them to be disgorged when half-digested. The case of the fourth specimen is more difficult to understand, but though moles are eaten by the common adder and by the four-rayed snake (*Coluber quatuor-radiatus*) of the Continent, it may be that lowering of the digestive powers caused by captivity was just enough to prevent any digestion of a new prey by a snake the natural diet of which is rodents and birds; and one is reminded of the belief of falconers that the eating of a moorhen puts the trained goshawk out of working condition, though it is not likely that the free bird abstains from such prey. But in any event, it is interesting to find that a reptile coming from a country where the summer is so much warmer than that of Great Britain can not only do well in an outdoor cage, but have sufficient energy to escape and find prey for itself, in such a poor summer for warmth as we have had this year.

THE strange acquirement of a Central Australian parrot, the Corella (*Kakatoa sanguinolenta*), is described by A. W. Mullen in the *Australian Museum Magazine* for July. The individual in question is now twenty-six years old. When it was a year old, the owner's children were firing off crackers close to the bird's cage, when in terror it seized its loose drinking tin (a shallow preserved-meat tin) and placed it over its head—the writer says, "to hide what was to the parrot a terrifying scene". The action in itself was curious, but it is more extraordinary to learn that ever since then the parrot has placed the tin can on its head every night. "He places the tin on his head before falling asleep, and keeps it on like a night-cap until the first streak of dawn awakens him." When by day he had to be transported by rail, he clapped the tin over his head whenever he encountered the strange sights and sounds of the railway station. During his quarter of a century he has worn out at least four tins. We fear to speculate as to the thought which originated and continued this curious action, but remembering the imitativeness of parrots (this one talks and calls the children by name, as well as mimicking dogs and fowls), we wonder if his master ever wore a night-cap.

A STRIKING example of human concern for the well-being of wild fauna, apart from mere prevention of cruelty, has recently been set by the Viennese Society for the Protection of Birds. Owing to the very inclement weather in Austria at present, thousands of swallows have been stranded on their migration southwards. The Society has taken the problem into its hands and has collected the stranded birds, giving them sanctuary and food. The birds are then being sent over the Alps either by specially heated coaches attached to the night express train or in cases, which each hold 1000 birds, by aeroplane. The first consignment of 2000 birds was sent to Venice on Sept. 25, and, landing in a suitable climate, took to their wings, finally making their way south. On Sept. 26, 25,000 birds were sent by aeroplane. The weather was unsettled on Sept. 27, so 35,000 were sent to Venice by train. Thousands more are being dealt with, and after resting in Vienna will in due course be sent to Venice.

A LARGE number of visitors availed themselves of the invitation of Sir Joseph Petavel to attend a reception at the National Physical Laboratory on Sept. 24, arranged in connexion with the Faraday celebrations and the centenary meeting of the British Association. Each visitor was provided with a programme of exhibits, members of the staff were present to explain the various investigations being made, and by an excellent system of signs and numbers it was a simple matter to find any particular exhibit. Tea was served in the great building housing the new duplex wind tunnel. This tunnel is 14 ft. by 7 ft. in section, and in it models up to 7 ft. or 8 ft. span can be tested with air speeds up to 75 miles an hour. Another notable aeronautical exhibit was the compressed air tunnel, now nearing completion, in which models will be tested under an air pressure of 300 lb.

per sq. in., the air jet being 6 ft. in diameter. Whereas the other wind tunnels are built of wood, this tunnel has a steel shell 2½ in. thick and weighs 250 tons. It has been tested hydraulically to 500 lb. per sq. in. By the use of this tunnel, scale effect is eliminated, and the results of experiments are immediately applicable to the full-scale machine or component. In the William Froude Laboratory visitors were shown a model ship under test, and the methods of making the models. The demonstrations of flashover tests at 350 kv. on a porcelain insulator string in the High Voltage Laboratory also attracted many visitors. Throughout the laboratory every facility was afforded for learning what was being done, and the efforts of the members of the staff were much appreciated.

The extensive new laboratories of the Lancashire and Cheshire Coal Research Association were opened on Sept. 22 by Mr. R. A. Burrows, the first president of the Association. The Association was formed in 1918, the funds being provided voluntarily by eight of the large colliery firms in Lancashire. The organisation is now supported by the Lancashire and Cheshire Coal Owners' Association, which includes substantially all the collieries in the coalfield. The programme of work of the Research Association embraces the physical and chemical survey of the seams of the coalfield, the investigation of problems connected with safety in mines, and the study of coal mining. The coal survey work forms part of the National Coal Survey, and in 1922 the fuel research organisation of the Department of Scientific and Industrial Research provided grants to enable the work on the survey aspects of the Association's work to be expedited.

Dr. F. S. Sinnatt, of the Department of Scientific and Industrial Research, who was the first director of research to the Lancashire and Cheshire Coal Research Association, outlined its early history and development, and said that the staff has been favoured by the enthusiastic support of the coal owners of the district, and has been helped by the fact that there has been continuity of direction by the Council. Originally the Association was largely concerned with the problems of the utilisation of coal, but now its investigations embrace questions of safety and coal winning. Prof. J. S. Haldane, who is especially interested in the investigations connected with the Safety in Mines Research Board, welcomed the establishment of the new laboratories, and said that he regretted it had not been possible for him to come to Lancashire more frequently to help them in the work they were doing. A very large number of coal owners from the Lancashire coalfield and fuel technologists from every part of the country inspected the laboratory, the details of which were explained by the director of research, Mr. Simpkin.

The report presented by the Seismological Committee to the British Association contains, besides references to the death of the late chairman, Prof. H. H. Turner, the revision of the seismological tables, and work on deep-focus earthquakes, an interesting note on recent earthquakes by Messrs. A. W. Lee, R. Stoneley, and F. J. W. Whipple. A map of the North Sea earthquake of June 7, depending on about 400 observations, has been prepared by Dr. H. C. Versey and Mr. Stoneley. The shock was felt at Waterford, in the Channel Islands, the north of France, in Belgium, Holland, and Denmark, and so far east as Hamburg and Brunswick. The epicentre indicated by the map agrees closely with the position assigned to it by the Rev. J. P. Rowland, *S.J.* (see Nature, vol. 128, p. 147, July 25, 1931). It lies under the North Sea, near the Dogger Bank, and about 60 miles from the coasts of Yorkshire and Norfolk. The spacing of the isoseismal lines suggests that the focus was decidedly deeper than in most British earthquakes. The seismograph records show, however, that it was not below the granitic layer.

A representative party of twenty members of the University of St. Andrews, officially accredited by the University Court and travelling under the auspices of the Overseas Education League (see Nature, Aug. 1, p. 196), returned to Southampton on Sept. 26 from an enjoyable and highly successful visit to the provinces of Quebec and Ontario. Throughout their tour the visitors were cordially welcomed by civic and educational authorities and in private homes, and special facilities were placed at their disposal so as to enable them to see as much as possible, in a limited time, of Canadian life, institutions, activities, and resources. The group was officially entertained by the cities of Montreal, Toronto, and Hamilton, by McGill, McMaster, and Queen's Universities, and by the Universities of Toronto and Western Ontario. In Quebec, the members were received by the Lieutenant-Governor at 'Spencer Wood', and were the guests of the Provincial Department of Public Instruction at Kent House, Montmorency Falls. At Montreal, visits were also made to Macdonald College and the Université de Montréal; at Toronto, to the Canadian National Exhibition and Lake Simcoe; at Ottawa, to the National Research Laboratories and the Gatineau district; at Hamilton, to Queenston and Niagara Falls; and at Kingston, to the Royal Military College and the Thousand Islands.

At a farewell dinner, given to the visitors from St. Andrews, at the Chateau Frontenac, Quebec, by Mr. E. W. Beatty, president of the Canadian Pacific Railway and Chancellor of McGill University, Prof. John Read, leader of the party, stressed the importance of such tours as a factor in education and in promoting understanding between Great Britain and the overseas Dominions. He expressed the hope that similar tours will follow this initial venture, and commented on the value of an interchange of teachers, as well as of an increasing number of post-graduate students, between Canadian and British universities. As one means to this end, he advocated the gradual establishment of non-resident lectureships in universities throughout the Empire. The Rev. Father Cannon, of Laval University, in giving the young Scots a glimpse of educational history in Quebec, explained the main factors which have enabled the French- and English-speaking Canadians to live together in harmony. At the conclusion of the evening, according to the *Chronicle-Telegraph*, Quebec, "the score of braw lads and lasses frae the auld grey toun, rose and sang 'Ygorra, Beatty', a version of their University song, in honour of the C.P. president".

THE *Polar Record* (Scott Polar Research Institute, Cambridge), in its July issue, maintains the high standard of usefulness shown in its first issue. There is again a full record of the activities of all exploring expeditions in both north and south polar regions and a great deal of material that is otherwise difficult of access. It is of interest to note that the Russian Academy of Sciences has been exploring the Indigirka region in eastern Siberia and has established several meteorological stations: also that a new research station is functioning in the little-known New Siberian Islands in lat. 73° 11′ N., long. 143° 15′ E. Stations have also been started in Franz Josef Land and, to the east, in the newly discovered Kamenev Islands. In an article on the Second Polar Expedition, 1932–33, Dr. G. C. Simpson gives a list of the many stations which various States propose to establish as their contribution to that international project.

IN discussing, in the issue of *Scientiarum Nuncius Radiophonicus* for July 30, the hypothesis that the penetrating rays originate in the 'annihilation of matter', Prof. Gianfranceschi points out that this expression is not readily acceptable by all. Annihilation of matter, in the sense applied to this process by Jeans and others, would give rise to energy in the form of photons, these being nuclei of radiant energy, which is a state of matter. It seems, therefore, preferable to say that the positive or negative corpuscles are transformed into primigenic matter, with liberation of a certain quantity of radiant energy, of which photons are composed. In this form the hypothesis is capable of wide extension. Electrons and protons are a special form of the universal primigenic matter, and both the formation of corpuscles within this matter and their dissolution to re-form the primigenic matter are possible. This universal primigenic matter is what constitutes space-ether, since, even in the hypotheses of the most advanced relativists, real space has physical properties and is hence a primigenic form of matter.

THE annual Henry Herbert Wills Memorial Lecture in physics at the University of Bristol will be given in the Wills Physical Laboratory by Prof. Niels Bohr on Oct. 5, at 5.15 P.M. Prof. Bohr will speak on "Space-Time Continuity in Atomic Physics".

THE 1931 award of the Ferranti Scholarship of the Institution of Electrical Engineers (annual value £250, tenable for two years) has been awarded to W. G. Thompson, of Armstrong College, Newcastle-on-Tyne.

THE inaugural sessional address of the Pharmaceutical Society of Great Britain will be delivered by Prof. G. E. Gask, dean of the Faculty of Medicine in the University of London, on Oct. 7. The presentation will also be made of the Pereira Medal of the Society.

THE Foreign Work Committee of Leplay House is arranging to take a group to Italy during the coming Christmas vacation. Rome and Naples will be the centres from which Oetia, Tusculum, Herculaneum, Pompeii, Paestum and other places of interest from the archæological, historical, and sociological point of view will be visited. For full particulars application should be made to Miss Tatton, Director, Foreign Work Committee, Leplay House, 65 Belgrave Road, Westminster, S.W.1.

MESSRS. Ernst Leitz, of Wetzlar (London Branch, 20 Mortimer Street, W.1), have recently completed their 300,000th microscope, which, in accordance with their usual custom of dedicating each 50,000th microscope to a well-known scientific worker or institution, has in this instance been presented to Prof. Ludwig Aschoff, of the Pathological Department of the University of Freiburg. This microscope, in addition to having valuable apochromatic objectives, is equipped with the new Ultropaque illuminator (working in incident light) and the complete set of fifteen new objectives specially constructed for this illuminator. The Ultropaque arrangement, which is a recent innovation, has already proved of value in cancer research and in the investigation of living tissues in general. Previous gifts of Leitz microscopes, each marking the completion of 50,000 instruments, have been made to the German Sanatorium for Consumptives, Davos, Switzerland; Robert Koch; Paul Ehrlich; Prof. M. Heidenheim; and the Institut für Schiffs- und Tropenkrankheiten, Hamburg.

MESSRS. W. and G. Foyle, Ltd., 119 Charing Cross Road, W.C.2, have just circulated a comprehensive catalogue (Dept. 7) of second-hand and new books on technical subjects and applied science. In many cases both the published price and that asked for second-hand copies is given—a useful feature.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A chemist-bacteriologist in a margarine factory in St. John's, Newfoundland—The Trade Commissioner, Newfoundland Government Offices, 58 Victoria Street, S.W.1 (Oct. 8). An honours graduate in chemistry at the Wolverhampton Municipal Secondary School—The Director of Education, Wolverhampton (Oct. 10). A London representative of the New Zealand Fruit-Export Control Board—The Secretary, New Zealand Fruit-Export Control Board, Box 882, Wellington, New Zealand (Nov. 30). A lecturer in chemistry at the Handsworth Technical College—The Principal, Handsworth Technical College, Handsworth, Birmingham. A lecturer in the building trades department of the Cape Technical College—Chalmers and Guthrie (Merchants), Ltd., 9 Idol Lane, E.C.3. A chief mathematical master at the Swansea Grammar School—The Director of Education, Dynevor Place, Swansea.

ERRATUM.—In the announcement of Messrs. G Bell and Sons' standard and new science books in last week's issue of NATURE, the title of Prof. E. N. da C. Andrade's "The Structure of the Atom" was incorrectly printed as "The Mechanics of the Atom", and that of his "The Mechanism of Nature" as "The Mechanics of Nature".

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Isolated Quantised Magnetic Poles.

IN the last number of the *Proceedings of the Royal Society,* Dirac has come to the conclusion that the quantum theory requires the existence of discrete magnetic poles of a strength equal to 137÷2 times the electronic charge. If such objects were common one might expect the universe to be a good deal different from what experimenters have found it to be, so far.

There seems no a priori reason why the whole theory of atom building which has been built up for electrons and nuclei—an electrostatic problem apart from details—should not be carried over bodily into the corresponding magneto-static problem of the attractions of the oppositely charged poles. In this way we might, at first, expect to get a set of 'magnetic' atoms, similar to the electric atoms of which matter is generally supposed to be built up. These atoms would be a good deal different from those we think we are familiar with. How much different depends to some extent on what the mass of a magnetic pole is. The quantum theory does not tell this, but I think its value, if it exists, can be fixed by an argument based on classical ideas at about 500 times that of the corresponding electronic object. Following this general line of argument, the dimensions of these magnetic atoms come out at 10^{-14} cm. to 10^{-15} cm. compared with 10^{-7} cm. to 10^{-8} cm. for the atoms of the periodic table. The frequencies of the 'spectral' lines emitted by these magnetically constructed atoms would run about 10^{10} times those of the corresponding lines of the electronic spectra; for example, the first line of the Lyman series would be raised from $\nu = 2{\cdot}5 \times 10^{15}$ to $\nu = 3{\cdot}1 \times 10^{25}$ sec.$^{-1}$ if the corresponding states are capable of existence. Even if quite large changes are made in the mass of the magnetic poles, which is the doubtful element, the corresponding numbers will still remain quite wide apart.

Dirac has suggested that the reason these magnetic poles have not been observed may be that the forces between them are so much larger than those between electrons and protons that they cannot be separated. There is reason for believing they could not get together to the extent indicated by the preceding numbers. The number of kinds of atoms with azimuthal quantum number 1 which can be formed from these magnetic units is much less than unity. This follows from Dirac's formula for the spectral terms for hydrogen, or alternatively, from the principle of minimum time. This may be forcing the required atoms too much into the pattern of those with which we are familiar. In any event, no atom with azimuthal quantum number less than 34½ can be made out of these elements. Otherwise the time factors in the wave functions involve real exponentials and become infinite with lapse of time. However, even with such high quantum numbers the forces would still be enormous compared with those in corresponding electronic structures and the frequencies would still be quite high.

There may be an application of these products of the quantum theory in the field of 'ultra-penetrating' radiations. I have no first-hand knowledge of the process of creation, but I should suspect it would be relatively difficult to create objects with the intrinsic energy of these magnetic poles. It seems likely, therefore, that their abundance would be very small compared with that of electrons and protons, but there might be enough in the universe to account for such ultra-penetrating radiations as are not capable of being accounted for otherwise. The possible existence of such isolated magnetic poles, with properties so very different from those of electrons and protons, obviously changes the basis for discussion of a good many cosmological questions.

O. W. RICHARDSON.

Sept. 18.

Similarity between Cosmic Rays and Gamma Rays.

As heretofore indicated,[1] it was in the fall of 1926 that Millikan and Cameron began to use high pressure electroscopes in order to increase the sensibility of their cosmic ray measurements. They built at first two such electroscopes and filled them to pressures of 8 atmospheres and 30 atmospheres respectively. Their first published results [1] were obtained with the 8-atmosphere filling, and they then assumed that for these hard rays the observed ionisation would be proportional to pressure. By directly comparing, however, a little later, similar spherical electroscopes of 1600 c.c. capacity filled to 1 atmosphere and to 8 and 30 atmospheres respectively, they were surprised to find that the ionisation shown in the 8-atmosphere electroscope was but about five times, and that in the 30-atmosphere electroscope was but 13·8 times that in the 1-atmosphere electroscope. These facts were published in one of their 1930 publications,[2] but since the authors were then interested merely in the *variation* in the ionisation in a given electroscope with depth beneath the top of the atmosphere, they made no attempt to discuss the reasons for these low factors. They did, however, *by direct comparisons find that these factors were the same for the gamma rays of radium and thorium as for the cosmic rays, thus bringing to light another significant similarity in behaviour of these two types of radiations.*[3]

Since Broxon [4] and Hoffmann [5] have both, in recent publications, commented upon these pressure-ionisation relations as measured by them, in entire agreement too with our own measurements, but without directing attention to what we consider to be the correct explanation of the phenomena, we have decided to present it herewith in this brief note. There are two causes of this failure, even for very hard rays, of the expected linear relation between pressure and ionisation. The first and the less important of the two is that mentioned by Hoffmann, namely, the mixture with the hardest beta rays which are formed by Compton-encounters with the original cosmic ray photons, of soft secondary beta rays which may be fully absorbed even within the air of the electroscope at 1 atmosphere, and can contribute no more to the ionisation when the pressure is high than when it is low. We have reasons which, merely for brevity's sake, we omit from this brief note, for thinking this cause of departure from linearity in the pressure-ionisation curve to be relatively small. The main cause of divergence from this relation is the following.

The low energy electrons shaken loose by the original ionising beta ray, if thrown an appreciable distance from the parent positive atom at 1 atmosphere, could be thrown but a small fraction of this distance at 8 atmospheres or at 30 atmospheres. The tendency to recombine then increases very rapidly with pressure. This lack of saturation effect will scarcely be noticed at all when the impressed field is varied from, say, 100 volts to 300 volts as in our own experiments. In other words, for such fields the ionisation currents will give all the usual indications of being saturated, though very strong variations of field rising up to thousands of volts, should bring to light the fact that they are not. *This lack of saturation is then, in our judgment—and we have experimental evidence for it—the real cause of the pressure-ionisation effects discussed otherwise by Hoffmann and Broxon.*

Graphical Indication of Humidity in the Upper Air.

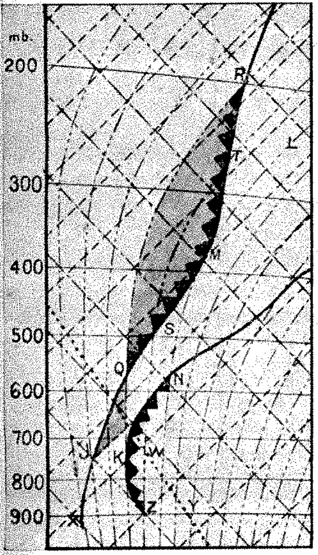

FIG. 1.—Tephigram and estegram: ——, isobars ; – – – –, isentropics ; —·—, isothermals ; . . . . . ., isohygric ; —·–·–·—, saturation adiabatics.

SIR NAPIER SHAW'S representation of upper air temperatures by the method of the T-ϕ or tephigram is, from the thermodynamical aspect, the best that has yet been proposed. The depegram (or graph of dew-point temperatures), which ordinarily accompanies it, is a practical means of representing humidity, yet most meteorologists will agree that it is not as wholly satisfying a method for humidity as the tephigram is for temperature. A thermodynamic indication of humidity along with the tephigram is of importance, especially in the tropics, and further consideration of the mode of representing humidity is therefore desirable.

In the accompanying diagram (Fig. 1), X the dry bulb and Y the dew-point temperatures at the 900 mb. level, are plotted on tephi-paper. The isentropic XW and the isohygric (or line of constant specific humidity) YW are drawn and intersect at W. Through W is drawn the saturation adiabatic WZ, cutting the 900 isobar at Z. We may call Z the 'saturation' temperature or *S.T.*, and direct attention to the following important properties: The *S.T.* is so nearly the same as the ventilated wet bulb temperature that in practice they may be substituted for one another.[1] If a sample of the air at the 900 mb. level is raised adiabatically, the dry bulb temperature of that sample moves along the isentropic XW, the dew-point temperature along the isohygric YW, and the saturation temperature along the saturation adiabatic ZW. The air becomes saturated at W, all the three temperatures coincide there, and further upward displacement causes them to follow the saturation adiabatic WST. Beyond T the saturation adiabatic runs parallel to a dry isentropic; that is, it is associated with, and can be identified by, a definite value on the potential temperature scale. That potential value of the *S.T.* (or wet bulb) is allied to the equivalent potential temperature; it remains an invariant in all adiabatic processes whether the air is saturated or not.

If the saturation temperatures or the wet-bulb temperatures of the upper air be plotted on the appropriate isobars or tephigram paper, the resulting graph of *S.T.*'s, or estegram, proves to be of greater importance thermodynamically than the depegram. We may note the following points:

(1) From any two of the three graphs, tephigram, estegram, and depegram, the third may be readily constructed on tephi-paper without reference to tables.

(2) If we define air of latent instability to be air which, when raised adiabatically, finds at some level above the condensation level an environment in which it is unstable, then all air samples of latent instability are indicated by the points on the estegram that lie to the left of the lowest saturation adiabat tangential to the tephigram. For example, LMN is the lowest saturation adiabat tangential to the tephigram $XQMR$, and to the left of it lies the portion ZN of the estegram; hence the layers of air between the heights represented by Z and N are those which on adiabatic ascent will develop instability in another higher layer.

(3) Superadiabatic gradients being excepted, all layers which form a latent unstable environment for samples of air displaced adiabatically upwards from one or more of the lower layers are indicated by points on the tephigram which lie to the right of the highest saturation adiabat tangential to the estegram. For example, KQR is the highest saturation adiabat that touches the estegram, and to the right of it lies the portion QMR of the tephigram; Q and R therefore represent the limiting heights between which instability may arise on account of the adiabatic ascent of a lower layer.

(4) If the lowest saturation adiabatic tangential to the tephigram lies wholly to the left of the estegram, then no layer possesses latent instability. This is frequently the condition of continental air in India. On the other hand, oceanic equatorial air seems frequently to possess so marked a latent instability that samples of the lower air when raised adiabatically will release more energy during the higher unstable portion of their ascent than is needed to be supplied in the lower stable portion. The point J on the diagram (with *S.T.* at K) represents such an air sample, because the area QRM represents a much greater release of energy than needs to be supplied to raise the sample from J to Q.

A classification of Indian tephigrams, suggested by the above considerations, is being undertaken by a research student.

Activated Adsorption.

THE transition from van der Waal's adsorption to activated adsorption is shown by a minimum on the adsorption isobar,[1] and a similar minimum occurs on the isobar representing the transition from activated adsorption to chemisorption.[2] There is thus a region of temperature over which the amount of adsorption increases with rise in temperature. The experimental work so far published shows that, at least in the case of the first type of transition, the processes are reversible. The positive temperature coefficient must therefore be associated with an increase in the heat of adsorption.

If ϕ be the activation energy of the surface atoms and Q the heat liberated on adsorption, then at constant pressure the number of surface atoms which are covered by gas molecules will be given by $N' = N . e^{(Q-\phi)/RT} . k$, where k is a constant but slightly affected by temperature. In the above transitional regions, $Q - \phi$ must possess at first a negative value, ultimately becoming zero and then positive. It is unlikely that ϕ will decrease with increase in temperature, therefore Q must become larger as the temperature is raised. There are but few experimental data bearing on this point. The heat of adsorption of oxygen on charcoal, for the same amount of gas adsorbed, increases from 70 to 110 k.cal. as the temperature increases from 20° to 110° C.[3] From 100° to 200° C. the heat is practically constant. These values probably refer to a transitional region between van der Waals and chemisorption, but this is somewhat uncertain. The figures, however, lend support to the above view, that the heat of adsorption in the transitional regions increases with rise in temperature. More experimental work is needed on the effect of temperature on the heat of adsorption.

The activated surface atoms will undoubtedly be mainly singlets at low temperatures, but doublets will increase in number as the temperature is raised. The increase in the heat of adsorption may be due to this fact, for the energy liberated on adsorption will probably be the greater the more activated the group of surface atoms by which the adsorbed molecule is held.

Change of Dielectric Polarisation of Nitrobenzene with Temperature.

Recently one of us (J. M.) has determined the changes of density D and dielectric constant E of nitrobenzene with temperature.[1] In this connexion we would like to repeat here that the freezing point of nitrobenzene lies at 5·5° C. and not at 9° as given in the Landolt-Börnstein tables.

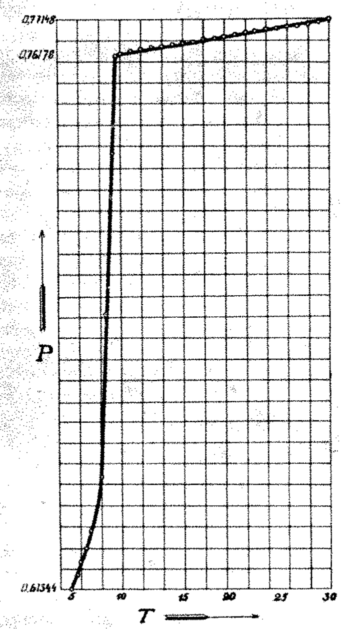

Fig. 1.

On the basis of these data, we have computed the dielectric polarisation P of nitrobenzene, according to the formula of Clausius-Mossotti,

$$P = \frac{E-1}{E+2}\frac{1}{D}$$

The results of this computation for the temperatures between 5·5° C. and 30° C. are represented on the accompanying curve (Fig. 1).

The value of P changes linearly with temperature, varying from 30° down to 9·6°. At 9·6° there appears a sudden drop in the value of P. This suggests that at the point 9·6° (which, as our former studies have shown, is a transition point from one liquid modification of nitrobenzene into another one, also liquid) the structure of the molecule undergoes a change. We have therefore to do here with a phenomenon somewhat different from that appearing in liquid helium, where the structure of the molecule does not undergo a change.[2]

The summary of the results we have obtained with nitrobenzene can be stated as follows: at the point 9·6° there appears to be a jump of the value of dielectric constant; a distinct change of slope in the density curve, and a very distinct change in the value of the refractive index.

Charged Aerosols and Ball Lightning.

Messrs. Cawood and Patterson conclude their extremely interesting account of the behaviour of electrified aerosols with the comment:[1] "The existence of such a spherical highly charged assemblage of particles suggests that globular lightning may owe its origin to an analogous effect, in which particulate matter, either liquid or solid, is charged to a very much higher potential".

Is it advisable to consider only liquid and solid particulate matter in this connexion?

Is it not conceivable that gaseous molecules, if charged to a sufficiently high potential, may mutually repel each other so strongly that the properties of the assemblage cease to be that of a similar one subject only to ordinary Maxwellian thermal movements, forming temporarily an unstable expanded mass, perhaps of considerable tenuity, surrounded by normal gas at ordinary pressure?

Puzzling features of ball lightning are the violent explosions which sometimes occur inside a room, without damage to persons present or furniture.[2, 3]

If an attenuated electrified mass of gas can suddenly collapse, like an evacuated electric light bulb, it would afford an explanation of this mysterious behaviour.

During the explosion of certain gaseous mixtures, charged molecules which are not subject entirely to Maxwellian thermal movements, temporarily, may complicate the phenomena.

Exceptionally high voltages can now be developed in a few research stations; further research may reveal the conditions under which the charged aerosol behaviour can be extended to gases.

Resonance Spectrum of Hydrogen.

WHILE we were attempting to photograph the spectrum of arsenic by the Paschen hollow cathode discharge in helium, plates were obtained which revealed with remarkable intensity the Lyman series of hydrogen extending down to the 15th member. The most interesting feature of the series, however, is the peculiar distribution of intensity among its members. Instead of the intensity diminishing steadily to the very last member, it diminishes rather slowly to the 10th member; there is a definite increase in intensity of the 11th and then an abrupt fall, so that the remaining members are only just observable.

Further experiments under varying conditions of pressure of helium and arsenic in the discharge have definitely indicated that the phenomenon must be interpreted as a case of resonance occurring only in the presence of arsenic. With a high pressure of arsenic and a low pressure of helium, the 10th and the 11th members of the Lyman series appear with considerable intensity (the 11th being stronger), while the others show a rapid diminution in intensity, the 8th and 9th being very faint.

It is considered that the energy of excitation of this resonance spectrum is to be sought for in a transfer, by collisions of the second kind, from the excited arsenic atoms. Further investigations are in progress to determine the exact value, from series data, of the first ionisation potential of arsenic, a knowledge of which throws considerable light on the correct interpretation of the phenomenon.

A full report of the results will be published as soon as they are ready.

Contraction Constants of Enzyme-Substrate Reactions.

CHANGES of volume accompanying enzyme hydrolysis have been utilised by Sreenivasaya and Sastry[1] to follow the kinetics of enzyme action by means of the dilatometer. The procedure employed in the above investigation does not bring into consideration the substantial volume change occurring in the initial stages of the reaction, and therefore gives no idea of the total contraction resulting from the complete hydrolysis of the substrates. The total contraction given by an enzyme-substrate system depends only on the absolute amount of the substrate in the reaction mixture, and is proportional to it.

The contraction of a few systems has now been investigated by a specially designed dilatometer; the contraction per gram-molecule of the substrate has been calculated, and found to be a constant for each enzyme-substrate system. For urea-urease the constant is 24, while sucrose-invertase has a constant of 6. These constants are of considerable value in the dilatometric estimation of substrates in physiological liquids and plant saps. Constants for other enzyme-substrate systems are being determined.

The Treatment of 'Gapes' in Chickens.

OUTBREAKS of 'gapes' among chickens usually lead to a very high mortality. The disease is due to the presence of the nematode worm *Syngamus trachealis* Lieb. in the windpipe. Treatment with turpentine in olive oil, applied with a feather, is often successful in skilful hands, but I have only saved one pullet thus. A severe outbreak occurred among my chickens in March 1930, and I treated a number with carbon tetrachloride dissolved in medicinal paraffin, probably about a two per cent solution. Fewer died than I expected, but being otherwise occupied, no records were kept.

In January this year four chickens were hatched out, and all developed gapes when about a month old. Two died, and I started to treat the remaining two cockerels by giving, on three successive nights, about 2 c.c. of carbon tetrachloride solution, administered by means of a pipette with teat. Though one appeared to be very ill at the start, both recovered. Successive outbreaks were similarly treated, fourteen birds in all, with only one death up to about the end of May. The birds were usually a month or six weeks old when attacked. Late in May, however, gapes appeared in two broods, of eight and six, when about a fortnight old. The treatment failed completely, and thirteen died, even though the amount of carbon tetrachloride was increased up to probably about five per cent. One pullet, however, never contracted gapes, though she must have been as heavily infected as the others. This bird is still alive, and might form the starting point of an immune race.

Though unsuccessful among chickens a fortnight old, the treatment has undoubtedly been successful among older birds, and appears to be worth the attention of those engaged in work on poultry. My own trials were rather rough and ready, a cure rather than a definite research being the object. The breeds were Light Sussex and White Wyandotte, including crosses.

A Spark Method of Measuring High Resistance.

A CONDENSER of capacity $c\mu f$ charged through a resistance r megohm by a battery of e volts, has at any instant a charge $q = ec(1 - \epsilon^{-t/cr})$. After a time, t sec., the charge is approximately equal to 2/3 ec. The attainment of this stage in the charging process may be determined by inserting a spark gap in parallel with the condenser, of which the sparking potential is 2/3 e, the spark passing when $t = cr$.

This suggests a method of measuring resistances of a high order (or capacities of a low order), and some preliminary experiments have been made with standard megohms and xylol alcohol resistances of the order of 10^8 ohm. The spark gap consisted of two platinum wires about 1 mm. apart fused into a highly evacuated glass tube, the sparking potential being about 410 volts. The values obtained for the resistances in this manner were about 10-15 per cent too great, but consistent results were obtained in all cases. The large results (that is, large values of t) obtained are probably due to leakage through the condenser insulation or across the glass of the spark tube. The elimination of these defects is under investigation, and it is hoped shortly to publish elsewhere the results of further work.

London, Aug. 17.

Research Items.

A Late La Tène Spear-head from the Thames.—In *Man* for September, Mr. T. D. Kendrick describes and figures a remarkable ornamented iron spear-head found in the Thames at London and now in the possession of Captain Ball. It is 11·8 inches long and has a broad triangular blade with rounded base angles. The wings are flat; but the blade itself is bisected on each face by a raised mid-rib, sharp-edged and triangular in section. This extends from tip to base, where it merges into the socket, which is faceted for a short length and then runs on round-sectioned. The forging is excellent and shows no trace of the annealed joint. Bronze plates are affixed to the lower part of the wings on each face—thin strips of metal with bevelled edges about 3½ inches long. They are applied as four separate pieces, being fastened in position by a number of neat little pins, of which two have the heads traversed by the ornament on the plates. No two of the plates are alike, but each is cut into a sinuous form with eccentric leaf-shaped protuberances, and each is ornamented with an incised design in which a disc-ended S-shaped scroll, set off against a basket-work background, is the principal element. The pattern is not in the best tradition of this sort of work. The form of the spear-head would suffice to date it to the La Tène period. A large number of decorated spear-heads have been found abroad and some in Ireland. Yet this single English specimen is unique among all decorated La Tène spear-heads because of the manner of its ornament. Other spear-heads are decorated by inlay or by incised or openwork devices in the iron blade, but here it is in the form of applied plates of a different metal. In richness of decoration it is surpassed by a specimen from Hungary and one from Switzerland; but it is much later than either. It belongs to the middle of the first century A.D., and must be regarded as an important document for the study of 'Celtic' art in Britain, marking the complete disappearance of the fluid elegance of the earlier foliate design.

Speed of Flight of Birds.—An important contribution to our knowledge of the speed of flying birds is made by T. H. Harrisson in *British Birds* (Sept., p. 86). The data were obtained by well-designed methods of using a motor-car and motor-cycle; they cover 103 records for thirty-six species, and they refer only to normal daily flight. Comparison of the figures here with those which have been published by other observers suggests that in some species at least (for example, rook, swallow, and lapwing) there may be a difference between the speed of migratory and of normal daily flight. But it is evident also that speed for a species is not a constant: ten sets of records for the starling give speeds ranging from 48 to 24 miles an hour, the non-migratory speeds ranging from 32 to 24 m.p.h.; and eight readings gave the ring-dove a range from 51 to 27 m.p.h. The speeds of different species show striking differences: the fastest speed recorded by the author was 59 m.p.h. for a stock-dove, the slowest 17 m.p.h. for a herring-gull, and the seemingly slow tawny owl gave speeds of 45 and 41 m.p.h., while the swallow (eleven observations) yielded no better than a range from 23 to 32 and an average of 27·3 m.p.h.

Japanese Nematodes.—Dr. Shigemoto Imamura in his paper "Nematodes in the Paddy Field" (*Journal of the College of Agriculture*, Imperial University of Tokyo, vol. 11, No. 2; 1931) investigates the nematodes of the rice fields and their numbers before and after irrigation. This is an exceedingly interesting and important subject. Forty-eight species belonging to twenty-five genera are described and figured. The Anguillulidæ are by far the most numerous, amounting to more than seventy-five per cent of all those found in the fields before irrigation. The worms belonging to this family are more or less injurious to the higher plants, and it is found that after irrigation their numbers are reduced to less than one-third. The whole nematode population after irrigation was reduced to about half as many as before, but whereas before irrigation they were chiefly those which were injurious to the crops, after irrigation they were chiefly those which fed on other animals, including the Anguillulidæ, the predatory genus *Mononchus* being much to the fore. The results of these investigations suggest that the irrigation either causes the injurious nematodes to be drowned or to be devoured by other nematodes such as *Mononchus*. Most of the nematodes both before and after irrigation occurred in the layer of soil in which were the roots of the rice plants.

Duration of the Pleistocene Period.—An address to the American Association for the Advancement of Science by G. F. Kay on the classification and duration of the Pleistocene is published in the *Bull. Geol. Soc. Amer.*, **42**, pp. 425-466, 1931. Reasons are given for the interpretation that Pleistocene history involves four cycles from the time of advance of the first ice-sheet, the Nebraskan, to the retreat of the last, the Wisconsin, each being recorded in the deposits laid down during the early glacial stage and in the changes which those deposits underwent during the interglacial stage. New names have been chosen for the four epochs so defined: *Grandian* (Nebraskan and Aftonian), *Ottumwan* (Kansan and Yarmouth), *Centralian* (Illinoian and Sangamon), and *Eldoran* (Iowan, Peorian, and Wisconsin). The evidence used in estimating the durations of the interglacial stages was gained from field studies in Iowa of the relative depths of the leaching of calcium carbonate in similar materials which throughout their times of leaching were similarly situated topographically and climatically. The results in years are: post-late Wisconsin, 25,000; post-Iowan, 55,000; Sangamon, 120,000; Yarmouth, 300,000; and Aftonian, 200,000. The *minimum* duration of the times of actual glaciation is estimated at 30,000 years. The combined estimates give for the whole of the Pleistocene in Iowa a minimum of about 700,000 years. In so far as the rate of downward leaching may well have decreased as the depth increased, it is judged that the Pleistocene deposits may actually represent a much longer time, possibly up to two million years.

A Connexion between Electricity and Magnetism.—It is invariably found in experimental investigations that magnetic poles have to be dealt with in quantities equal in amount and opposite in sign. With the usual method of formulation, this fact is taken over into quantum mechanics, which is thus applicable only when there are no isolated magnetic poles. In a paper in the September number of the *Proceedings of the Royal Society*, Dr. P. A. M. Dirac shows that this restriction can be removed by a natural development of quantum mechanics. The new theory leads to a simple formula $hc/2\pi e\mu_0 = 2$, where μ_0 is a quantum of magnetic pole strength and the other symbols have their conventional significance. Comparing this with the well-known relation $hc/2\pi e^2 = 137$, which is known to be closely true from experiment independently of any theory, shows that $\mu_0/e = 137/2$. In other words, the attractive forces between two one-quantum poles of opposite sign is almost 5000 times that between electron and proton, a result which may explain why a separation of poles of opposite sign has never been effected.

Estimation of Dissolved Metals.—In the September number of the *Proceedings of the Royal Society*, F. Twyman and C. S. Hitchen describe an improved spectrophotometric method for the estimation of metals in solutions. It consists in principle in the measurement of the intensity of a line from its length in the spectrum photograph obtained when a disc of special contour is rotated in front of the slit of the spectrograph during the exposure. Much attention has to be paid to details of procedure, such as the operation of the spark source of light and the development of the plate, but it appears that the necessary operations, which are described in full detail, are neither unduly laborious nor intrinsically difficult. The method, as given for minor constituents in solutions of metals, seems to have as great advantages as the corresponding method for the analysis of alloys; it is rapid, sufficiently accurate, and often superior in many respects to a chemical analysis, whilst the spectrogram gives a permanent record of the analysis.

Constitution of Cyanidin Chloride.—In a communication to the *Journal of the Indian Chemical Society*, vol. 8, p. 329, Dr. M. Nierenstein discusses the constitution of cyanidin chloride, a substance which is of interest both to chemists and to botanists on account of its relationship to the anthocyanidin pigments of flowers. Since cyanidin chloride breaks down on hydrolysis to phloroglucinol and protocatechuic acid, it is necessary to ascertain the mode in which the two nuclei of these products are linked in cyanidin. Willstätter ventured in 1914 to assign a definite structure to the latter compound, since it was supposed that it could be produced from the anthoxanthone quercetin by reduction. The fact that this reduction theory, though strongly favoured by Everest, Willstätter, and other chemists, appears to conflict with botanical evidence led Malkin and Nierenstein to reinvestigate the matter. These authors (*Jour. Amer. Chem. Soc.*, **52**, 2864; 1930) were able to show that reduction of quercetin leads to a dimolecular product, quercetylene chloride, and not to the monomolecular pentahydroxyflavylium chloride, which has the structure assigned by Willstätter to cyanidin chloride. It appears that both quercetylene chloride and pentahydroxyflavylium chloride have been identified with natural cyanidin chloride, but the evidence on which identity of composition is based is stated to be inconclusive. Furthermore, X-ray analyses of the natural cyanidin chloride and the synthetic product have revealed their dissimilarity. Thus there appears to be some doubt about the actual structure of cyanidin chloride. A possible solution of the problem, based on the fact that Freudenberg has reduced the compound to epicatechin, is tentatively suggested in the paper.

Astronomical Topics.

Detection of Neujmin's Comet, 1913 III.—Search for this comet has been going on for some months. A telegram from the U.A.I. Bureau, Copenhagen, on Sept. 26 announced that Dr. Nicholson, at Mount Wilson, had found it in the following position:

Sept. 17^d 12^h 18·0^m U.T., R.A. 4^h 43^m 48^s,
N. Decl. 38° 29′, Mag. 15. Daily motion +40^s, N. 9′.

It was stated that there was no nebulosity; this was frequently the case in 1913.

This position and the motion are satisfied within 1′ by the following elements, which are from the B.A.A. Handbook for 1931, with adjustments to period, eccentricity, and date of perihelion:

$$\begin{array}{rl} T & 1931\ \text{April}\ 29{\cdot}98\ \text{U.T.} \\ & \left.\begin{array}{llll} \omega & 346^\circ & 57' & 48'' \\ \Omega & 347 & 18 & 10 \\ i & 15 & 9 & 3 \end{array}\right\}\ 1931{\cdot}0 \\ & \begin{array}{llll} \phi & 50 & 47 & 54 \end{array} \\ \log q & 0{\cdot}18415 \\ \text{Period} & 17{\cdot}689\ \text{years.} \end{array}$$

EPHEMERIS FOR 0^h U.T.

	R.A.	N. Decl.	log r.	log Δ.
Oct. 2.	4^h 49^m 43^s	40°40′	0·3712	0·2566
10.	4 49 32	41 45	0·3828	0·2514
18.	4 46 31	42 42	0·3942	0·2475
26.	4 40 58	43 27	0·4054	0·2460

This comet must be ranked as belonging to Saturn's family; its orbit makes a close approach to that of Saturn in the region passed by the comet after aphelion. It is the second member of the family to be observed at a second apparition. Tuttle's comet has been observed at seven apparitions.

Collapsed Stars and Novæ.—Prof. E. A. Milne suggested, in the *Observatory* for May, that novæ are the result of the collapse of a star of ordinary density. This collapse may produce rotational instability and cause the star to split into two portions. These may then re-expand, which would give an ordinary binary star. A system like that of Sirius might result if the larger star re-expanded, while the smaller one retained its high density. The very great disparity in state of the components of Sirius, both presumably of the same age, might thus be explained.

Incidentally, Milne concludes, from the observed frequency of novæ, that every star is a nova at least once in its history. This suggests the question: Has the sun had the disease yet? The appulse of another star, which is the current explanation of the birth of the planetary system, would produce conditions in the sun that would bear some resemblance to an outburst of a nova. Milne ranks the nuclei of planetary nebulæ, also ex-novæ, and possibly the ordinary Wolf-Rayet stars, as collapsed stars that have a high density and a high temperature.

Velocity of Light from the Spiral Nebulæ.—Some months ago Prof. Perrine made the suggestion that the positions of the distant spirals with reference to stars in their vicinity should be observed at different times of the year, as a test whether they indicated the same velocity of light as that from bodies in our own galaxy. It was not anticipated that any difference would be shown, as ever since the Michelson-Morley experiment it has been generally accepted that light from any source gives the same measured velocity. It was, however, of considerable interest to make the experiment. This has been done by Mr. Gustaf Strömberg, using plates obtained with the 60-inch reflector at Mt. Wilson; the results are given in *Pubs. Astr. Soc. Pacific*, August 1931. They give the same aberration constant for the stars and the nebulæ within 0·006″, which is far below the limits of probable error. Hence the velocity of light from the nebulæ is not influenced by the large recessional speed (11,000 km./sec.) which Humason found for the nebulæ that were observed by Strömberg.

The International Illumination Congress.

THE International Illumination Congress, which took place on Sept. 1–19, was the first conference of this kind to be held in Great Britain. Something like twenty different countries were represented and the number of names on the official membership list exceeded 500. It may be recalled that the Congress consisted of two distinct sections: the initial period during which members visited in succession London, Glasgow, Edinburgh, Buxton, Sheffield, and Birmingham; and the subsequent stage, on Sept. 13–19, which took place at Cambridge and was devoted to the proceedings of the International Commission on Illumination. During the first period more than a hundred different papers on varied subjects were presented and discussed; at Cambridge, reports from the various national committees surveying progress in different fields or making suggestions for international action were presented, and in some cases effect was given to these suggestions by suitable resolutions.

The programme in London (Sept. 1–3) was mainly social. Such institutions as the National Physical Laboratory, the E.L.M.A. Lighting Service Bureau, the G.E.C. Research Laboratories at Wembley, and the training centre for gas engineers at Watson House were visited. At a luncheon given by the Gas Light and Coke Co. and the leading London electric supply undertakings on Sept. 2, the toast of the Congress was proposed by the Rt. Hon. George Lansbury, M.P., who, on behalf of H.M. Office of Works, had taken a keen interest in the floodlighting arrangements. On the evening of the following day there was also a dinner at the Dorchester Hotel, at which the president (Mr. C. C. Paterson) presided. There were also motor trips round the streets of London by night and a visit to the Croydon aerodrome, where night-flying by artificial light could be witnessed. But the most interesting event of the London programme was undoubtedly the steamboat trip from Westminster to the Port of London, the return journey of which was designed to enable visitors to inspect the floodlighting.

Much has been written regarding the floodlighting, which aroused extraordinary popular interest. It is stated that the crowds on the evening of Sept. 2, the opening day, were the greatest in London since Armistice night. It is impossible to describe this lighting in detail, but there were several features of exceptional interest. The most brilliant illumination (estimated at 20 foot-candles) was attained on Buckingham Palace, which received light from 183 projectors, each rated at 1500 watts; but the treatment of other buildings was artistic and successful, such as the floodlighting, by rose-coloured light, of Somerset House and the pleasing 'local lighting' of Thames House, which enabled its architectural features to be 'picked out' and the roof to be revealed by special strip reflectors. Considerable enterprise was shown in two examples of gas-lighting, the special treatment of Whitehall (bringing the illumination up to Class "A" standard, that is, a minimum of 2 foot-candles, which is attained in no other street in Great Britain) and the floodlighting with gas of St. James's Park. The latter, whilst very effective pictorially, is of considerable technical interest because of the novel gas-lighting projectors designed specially for this scheme. During September there were, however, more than fifty towns throughout the country where floodlighting installations were arranged; Edinburgh Castle may be mentioned as a most noteworthy and effective example of floodlighting.

The party left for Glasgow on Sept. 3. On the following morning, a civic welcome was extended to them by the Lord Provost at the Royal Technical College, where the sessions took place. At Glasgow there were three simultaneous sessions, devoted respectively to lighting developments, photometric precision, and daylight. The papers grouped under lighting developments were mainly descriptive. Miss C. Haslett and Miss Nora E. Millar put in a plea for better domestic lighting. Mr. C. W. Sully emphasised the importance of good lighting to electric supply undertakings, which should set up well-staffed 'lighting service' departments. Sig. C. Clerici reviewed recent progress in illuminating engineering in Italy. Mr. C. A. Atherton presented an informative paper surveying educational methods throughout the world and illustrating (by reproductions of posters, etc.) the effect of national characteristics.

In these three sessions twenty-seven papers were presented, so that one cannot do more than briefly indicate a few salient points. The chief item in Section 2 (Photometric Precision) was a comprehensive survey of photometry by the National Dutch Committee, in which reference was made to the unsatisfactory nature of the various existing photometric standards. There appear to be two alternative possibilities, either a standard based on physical photometry or one based on the use of tungsten lamps of known dimensions. The latter seems the more practical method. Other papers were designed to show the degree of precision possible in laboratory and commercial photometry. Thus R. Kovesligethy and P. Selenyi and also L. Simek (Czechoslovakia) indicated the possibility of confining errors to within 0·25 per cent. A useful contribution by B. P. Dudding and G. T. Winch led to the interesting conclusion that the error in visual photometry consists of two approximately equal portions, arising respectively from imperfect visual judgment and inaccuracies in establishing the standard electrical pressure at which lamps operate. A further inference may be made that, if suitable precautions are taken, laboratory photometry based on the use of photoelectric cells gives greater consistency than is attainable by visual methods. Of special interest was the analysis by A. K. Taylor (G.B.) and by J. Wetzel and A. Gouffé (France) of errors in portable photometers. In the discussion, the importance of accurate control of the current taken by the lamps in such photometers was emphasised; it is regarded as doubtful whether adequate precision can be obtained from customary types of ammeters or voltmeters, and more sensitive methods (based on the use of null-points and bridges, etc.) have been suggested by J. T. MacGregor Morris.

There were no less than ten papers included in the Section on Daylight Illumination, the authors of which were drawn from seven different countries. Of the three British papers, that by P. J. Waldram contained an informative survey of the development of legal aspects of access of natural light, and the corresponding photometric methods that have been evolved in Great Britain. There appears to be good basis for the suggestion that in buildings a minimum daylight factor of at least 0·2 per cent should be adopted. With the normal sky-brightness of 500 lux already approved by the International Commission on Illumination, this factor would correspond to a minimum of 1 foot-candle.

On the evening of Sept. 4 there was a civic reception in the City Chambers by the Lord Provost, followed by a tour of inspection of the lighting of streets in

Glasgow and its environs. The following day was devoted to a pleasant excursion on the Firth of Clyde, and on Sept. 6 the party travelled on to Edinburgh, breaking the journey at Gleneagles. It had been remarked that in Glasgow there was little or no floodlighting, whilst at Edinburgh attention had been concentrated on the illumination of the Castle, which on account of its commanding site is an ideal subject. Although the degree of brightness in this case was less than in some London installations, the effect was very fine, the inequalities in the illumination of the extensive surface of the walls operating as a positive advantage.

At Edinburgh also there was a very full programme of papers, no less than 34 being presented in the four sections dealing with public lighting, diffusing materials, aviation lighting, and physiological problems. The outstanding session, however, was that devoted to public lighting. This was undertaken jointly with the Association of Public Lighting Engineers, the eighth annual conference of which was being held simultaneously. The morning papers were mainly statistical. Contributions reviewing progress in gas and electric street lighting were presented by Sir Francis Goodenough and Mr. W. J. Jeffery. Of considerable scientific interest was the account by Mr. W. S. Stiles ("Mass Experiments in Street Lighting") of impressions of degree of glare, visibility, etc., gathered in Sheffield and Leicester by an appeal to a considerable number of observers.

The afternoon session resolved itself largely into a discussion of the British Standard Specification for Street Lighting, which was ably dealt with by the president (Mr. C. C. Paterson) and others. Modifications in the original specification were explained and the difference between 'methods of grouping' and 'criteria of excellence' illustrated. These papers gave rise to a good 'international' discussion, and the chairman (Dr. N. A. Halbertsma, of Holland) excited general admiration by his interpretations in three languages and his skilful guidance of the discussion. An informative contribution was that of C. Clerici (Italy), who described the lighting of the arterial road from Rome to Ostia, by means of 60 watt fittings 'staggered' at intervals of only 25 ft.—an example of remarkably close spacing. In the section on aviation lighting, the papers by H. N. Green ("The Light Distribution from Navigation Lamps") and the British National Committee ("Ground Lighting Equipment for Aviation") were of special merit. In Section 2, J. W. Ryde and B. C. Cooper were responsible for two papers dealing with the theory of opal glasses. Japan was responsible for three papers in this section. On Sept. 8, visitors left for Buxton, where the next sessions were held.

(*To be continued.*)

Photographic Analysis of Explosion Flames.*

IN principle the method usually employed for the photographic analysis of explosion flames is the same as that originally designed by Mallard and Le Chatelier fifty years ago. It consists in photographing the movements of the flame along a horizontal glass tube on a sensitised plate or film moving vertically at a suitable known velocity, thus obtaining (*inter alia*) a graph compounded of the two velocities, from which that of the flame at any point can be deduced. Mallard and Le Chatelier employed horizontal tubes of diameter between 1 and 3 centimetres in sections, each 1 metre long, connected in series by means of caoutchouc rings. The whole was focused, by means of a wide aperture lens, on a plate moving vertically with a known uniform velocity of about 1 metre per second.

As the plates used by Mallard and Le Chatelier were not sufficiently sensitive to give satisfactory records with feebly luminous flames, such as those of hydrogen-oxygen explosions, they employed explosive mixtures of carbon disulphide with either oxygen or nitric oxide, the flames of which are much more actinic, believing them to be typical of all explosive 'oxygen' or 'air' mixtures respectively. The behaviour of these mixtures on explosion was found to differ according as they were ignited at or near (*a*) the open, or (*b*) the closed end of a tube. In the former case the flame always proceeded for a certain distance along the tube at a practically uniform slow velocity, which was regarded as the true rate of propagation 'by conduction'. This initial 'uniform movement' was usually succeeded by an 'oscillatory period', the flame swinging backwards and forwards with increasing amplitude, and finally *either* dying out altogether *or* giving rise to 'detonation', according to circumstances. With some 'oxygen'-mixtures the initial period of uniform velocity was short, and appeared to be succeeded abruptly by 'detonation', without passing through any intermediate oscillatory period. When, however, the mixtures were ignited near the *closed* end of the tube, the forward movement of the flame was continuously accelerated until finally 'detonation' was set up. In 'detonation', where the explosion is propagated from layer to layer by 'adiabatic compression', the flame velocities are both uniform and high, usually of the order 2000 to 3000 metres per second.

The experimental method was developed and improved by the late Prof. H. B. Dixon and his collaborators in Manchester during the nineties of last century. They used a highly sensitive film rotating vertically on the periphery of a drum with a constant velocity (which, however, varied between 25 and 50 metres per second in different experiments), the explosion tube being placed at such a distance from the camera that the size of the image was about one-thirtieth of the flame. In this way they analysed the progress of an explosion from its origin up to the final attainment of its maximum force and velocity in 'detonation'. They also discovered (i) the wave of 'retonation', which is thrown back through the still burning or chemically active medium from the point where detonation starts (a phenomenon also independently discovered by Le Chatelier in 1900), (ii) the effects of collisions between two explosion waves, as well as of the passage of 'reflected waves' through the hot products of combustion behind the flame front.

Within recent years the experimental method has been further developed and improved in the laboratories at the Imperial College, South Kensington, chiefly by means of the new high-speed photographic machines designed by Mr. R. P. Fraser, which have so increased its analysing power that it is now possible to photograph and measure movements in explosive flames occurring periodically with frequencies up to 250,000 per second. With a new type of camera embodying the principle of a mirror revolving *in vacuo* at high constant velocity (16,000 r.p.m.) and projecting the image of the explosion flame on to a stationary film, we hope soon further to increase the analysing power four- or five-fold. So that in the near future we hope to be able to photograph and measure periodic flame-movements occurring with frequencies of a million per second.

---

* Substance of an evening discourse delivered before the British Association on Sept. 24 by Prof. William A. Bone, F.R.S.

The results already obtained have modified and corrected many of our former ideas concerning the nature of the initial phase of slow uniform flame-movement in gaseous explosions, and (*inter alia*) completely disproved the supposed 'law of flame speeds'. Indeed, it now seems probable that what Mallard and Le Chatelier visualised as flame propagation 'by conduction' is an ideal condition perhaps realisable only when a stagnant explosive mixture is ignited without impulse at the centre of a spherical vessel of infinite radius.

Important new information has been obtained regarding the influences of 'compression' and 'shock' waves upon the speeding up of combustion and flame movements during explosions; and it is now proved that the speed can be abruptly raised from a lower to a higher uniform value when a flame is overtaken by a 'shock' wave travelling in the same direction. Indeed, it has been shown that in such manner the flame-speed can be successively raised *per saltum* many times, and that it may assume any uniform value between the limits of that theoretically corresponding with propagation by 'conduction' and that due to propagation 'by adiabatic compression'.

Much new light has been thrown on what may be termed the 'pre-detonation' phase of explosion, when the flame is advancing at a speed greater than that of any 'shock' wave through the unburnt medium, and is therefore overtaking any such shock waves which are ahead of it. 'Detonation' is ultimately set up when a rapidly moving flame on the verge thereof is just about to overtake a shock wave immediately in front of it. Thereupon an 'ignition ahead' of the flame-front occurs, and immediately afterwards 'detonation' is set up. Indeed, during the 'pre-detonation' phase a series of successive such 'ignitions ahead' may occur, detonation being set up immediately after the last one.

We have obtained photographs analysing the phenomenon of 'spin' in detonation, which was first observed five years ago in detonations of moist $2CO + O_2$ mixtures by C. Campbell and D. W. Woodhead, working in the late H. B. Dixon's laboratory, and later confirmed in our laboratories at South Kensington. 'Spin' has also been observed in detonations of methane-oxygen, pentane-oxygen, undiluted acetylene, and other media, and apparently is caused by the helical rotation of a luminous 'head' of detonation in the flame front together with a long luminous 'tail' behind it. The pitch (L) and frequency (f) of such rotation in detonations of a given medium varies with the internal diameter (D) of the tube, so that, while the ratio L/D for diameters up to about 1 inch is constant, and nearly equal to 3·0, the helical velocity of the rotating 'head' of detonation is approximately of the same order, irrespective of the medium or of the tube diameter. Thus, in the case of a moist $2CO + O_2$ medium, which exhibits the phenomenon most markedly, $f = 44{,}000$ per sec., and $L = 3{\cdot}95$ cm. in a tube of 1·3 cm. internal diameter, the velocity of the 'head' of detonation along its helical path being 2500 metres per second.

These discoveries have necessitated revision of the old classic conception of 'detonation' and opened up new lines of inquiry concerning it.

Within recent years the photographic method has also been used for the purpose of analysing (i) ignition phenomena, including the 'induction' period of explosions, (ii) the influence of moisture upon explosions of carbonic oxide-oxygen mixtures, and (iii) the influence of strong electrical fields upon gaseous explosions.

The Construction of Man's Family Tree.*

SOMEWHERE about the year 1865 Ernest Haeckel drew a family tree to represent man's relationship to the rest of the animal kingdom. Neither Darwin nor Huxley were so daring. In 1871 Darwin went no further in his "Descent of Man" than to infer that "a member of the anthropomorphous subgroup gave birth to man". In 1863 the utmost Huxley adventured was the opinion that man had arisen by "the gradual modification of a man-like ape or from the same stem". Haeckel saw life as a great tree rooted deeply in the geological past with only the end-twigs peering through the surface of the earth into the present as living forms. The terminal twig on the extreme right of his tree represents humanity (*Homo sapiens*). Man, the gorilla, and the chimpanzee are made to emerge from the same terminal stem. Following this human-gorilla stem to the left downwards, we find shooting from it the orang twig, then at a still longer interval, the gibbon branch, then the old world monkeys, then those of the new world, and ultimately this primate stem merges with the stem of the prosimiæ or lemurs.

The facts which guided Haeckel were the multitude of structural points in common which could be explained only as an inheritance from a common ancestor. To convert his hypothesis into true history it was necessary to find the fossilised remains of his missing links; but very few of these were known in his day—Neanderthal man and Dryopithecus and Pliopithecus from the Miocene deposits of Europe. Haeckel depicted the human stem as breaking away from that leading on to the gorilla and the chimpanzee rather more than half-way through the Tertiary period. On Osborn's estimation in years, Haeckel thus gives man's antiquity at 20 or 25 millions of years.

In 1895 Dr. Eugen Dubois, in order to incorporate his newly discovered Pithecanthropus, showed the central stem as represented at first by a proceropithecus, the ancestor of the old world monkeys, then the prothylobates, the ancestor of the gibbons, then the prototype of the great anthropoid apes, followed by the Pithecanthropus type and finally the stem ending in the human form.

Some years previously Sir Arthur Keith was engaged with the dissection of some 300 specimens, gorillas, chimpanzees, etc., and the collection of records of human dissections, in the hope of arriving at a clear-cut explanation of the distribution of anatomical characters. In 1900 he drafted a chart to show the mass of data thus collected. He arrived at the conclusion that the evolution of posture gives the clue not only to the evolution of man but also to that of all the higher primates. There are only two main ways in which an animal can climb a tree—either with the body horizontal (pronograde) or upright (orthograde). Sir Arthur Keith concluded that an arboreal orthograde anthropoid had first diverged in a humanward direction in specialisation of spine, leg, and foot. It was on the trees and not on the ground that man first came by the initial stages of his posture and carriage.

What has happened in the last thirty years confirms the conviction that in the study of the gibbon is the key to the evolution of the great anthropoids and man. In 1910 the discovery of Propliopithecus in the older oligocene of Egypt extended the antiquity of what is apparently an ancestor of the gibbons, and presumably orthograde, for a good many million years. It affords a fixed point for speculation concerning the evolution of the orthograde posture. Prof. Osborn and Prof. Wood Jones, who exclude the other anthropoids from the ancestry of man, are prepared to accept Propliopithecus as an ancestor from which both man and the chimpanzee may have arisen.

---

* Substance of an evening discourse delivered before the British Association on Sept. 26 by Sir Arthur Keith, F.R.S.

Sir Arthur Keith's census showed so many anatomical characters in common in the big-bodied group, gorilla, chimpanzee, and orang, that he postulated a common ancestor for the big-bodied group. The discoveries of Dr. Foutan in the lower Miocene of Egypt (1920) of two orthograde primates, one the size of a gibbon, the other half-way between the gibbon and man, support his contention that the great orthograde primates evolved at the beginning of the Miocene. It was at this period, evidently one of great plasticity, that Sir Arthur Keith supposes the human line to have separated from the great anthropoids. Dr. W. K. Gregory also brings the human stem from the anthropoids at the beginning of the Miocene. They both give the human stem an antiquity of about 20 million years.

The human posture was completely evolved before the end of the pliocene period. Allowing two geological periods, the Miocene and the Pliocene, this represents about 18 million years for the evolution of the human characteristics of foot, leg, thigh, and pelvis. Beside Pithecanthropus we now know two other forms of early Pleistocene man, Eoanthropus and Sinanthropus. By the end of the Pleistocene, then, the human stem had been in existence long enough to have broken up into many divergent branches; but we are uncertain whether they represent the ancestors of any race now living. Hence in our tree we trace the living races to an early pleistocene ancestor not yet discovered.

It is not claimed that this formula explains all the facts. Prof. Wood Jones points out that the human body preserves many primitive features which have disappeared from those of anthropoids and of monkeys—features which Sir Arthur Keith thinks are to be explained not by modifying the family tree but by a fuller understanding of the laws of inheritance. In the United States, Dr. W. K. Gregory assigns a place to Australopithecus, the Taungs skull, nearest to man. Dr. A. H. Schultz, of Johns Hopkins University, has drafted a tree in which the gibbon and man are opposed as contrasted forms, while Prof. H. Fairfield Osborn excludes the anthropoidal stage from human ancestry.

Sir Arthur Keith concludes by giving his support to the form of man's family tree which was drafted by Haeckel sixty-five years ago. All are agreed that anthropoid and man have a common ancestry; it is merely the degree of relationship which is in dispute.

A Retrospect of Wireless Communication.*

SIR OLIVER LODGE said that, looking back over his connexion with wireless telegraphy, the first paper which had attracted his attention was one by Lord Kelvin in 1853 on "Transient Currents", which gave the theory of electric oscillations in a masterly manner considering that the idea of self-induction was not then born. Kelvin knew that electric energy could be stored in and released by a condenser in a manner analogous to that in which energy could be stored and released by a coiled spring, and, moreover, that the current resulting from the condenser discharge possessed properties akin to inertia or momentum. The discharge would consequently be of an oscillating character unless the circuit resistance exceeded a certain critical value, and the resulting spark a beaded band instead of a continuous band.

With a large enough condenser, oscillations should be slow enough to give a musical note. The frequency of the note depends on the capacity of the circuit and on its self-induction, which Kelvin spoke of as the "electrodynamic capacity of the discharging circuit". Such a musical note was exhibited by Sir Oliver at the Royal Institution in what was called a 'whistling spark', the pitch of which could be brought down to reach the tones of the human voice.

One factor the theory did not take into consideration was possible loss of energy by radiation, in the same way as a tuning-fork mounted on a sounding-board loses energy to the surrounding air, thus diminishing the time during which the charge would oscillate. At the time, such radiation was unsuspected, and in any case there were no means of detecting it.

The first to show that an electric discharge would generate radiation was Fitzgerald, who discussed the problem mathematically in a paper read before the British Association in 1880. In a further paper in 1883, he calculated the actual energy lost per second by a given condenser and self-induction and showed that it was proportional to the fourth power of the frequency. To obtain an efficient radiator it was necessary to work with a frequency of not less than one million cycles. Fitzgerald took as the basis of his research the results of Maxwell's investigations on electromagnetic theory

In 1865, Clerk Maxwell had attempted to treat mathematically what Faraday had long brooded over as the 'electric field', regarding it as distinct from matter and existing in the ether of space round the charged body. Maxwell evolved two sets of equations, one for the electrostatic field and another for the magnetic field surrounding a current. These he combined in an endeavour to discover the nature of the electromagnetic field. His result, which is now familiar to scientific workers, was the differential equation expressing wave motion. Fortunately, the separate electric and magnetic constants of the ether, which are immeasurable, did not enter into the expression except as a product, which experiments in Germany had shown to be capable of determination.

Maxwell set to work to determine experimentally the rate of propagation of the electromagnetic waves predicted by his theory, and obtained the surprising result that it was equal to the velocity of light.

Theories of light up to this time had treated the ether as an elastic solid capable of transmitting vibrations at a tremendous speed. No single theory had been able to account for all the phenomena of light, and Maxwell's theory, published in 1873 and representing a complete departure from accepted ideas, came as a revelation. His equations have formed the basis of all subsequent work on electromagnetic waves.

Attempts were soon made to verify Maxwell's theory experimentally by the production of ether waves by electro-magnetic means. In 1887 or 1888, Sir Oliver Lodge, working with closed condensers, obtained evidence of their existence in the form of nodes or loops characteristic of ether waves reflected back on themselves at the end of a wire attached to such condensers.

---

* Substance of an evening discourse delivered before the British Association on Sept. 26 by Sir Oliver Lodge.

At the same time, Hertz in Germany was making experiments on the way in which electric forces streamed out from a discharging conductor. Using an oscillatory circuit consisting of two widely separated plates joined by a wire, he was able to generate waves as Fitzgerald had predicted. These waves were generated in space and had such energy that they caused little sparks to be emitted by a conductor on which they fell. Hertz showed that Maxwell's theory would account for his radiation in every detail, and he made maps of the lines of force during each phase of the oscillation. These maps were published in NATURE in 1889, in a translation of Hertz's paper by Sir Oliver Lodge.

Other means of detecting the waves than by the scintillæ they produced were soon developed. Sir Oliver Lodge discovered the principle of the coherer which was afterwards improved by Branly, and in 1894 he showed that Hertz's waves combined with a Branly detector could be used for the sending and receiving of messages in Morse code.

At the same time, Marconi in Italy was studying the application of Hertzian waves to telegraphy, and in 1896 he came to England and was able to interest Sir William Preece, chief engineer to the Post Office, and to secure his co-operation. Marconi persevered with his experiments, and to him must be attributed the great success of wireless telegraphy.

About the same time Sir Oliver Lodge had realised the importance of selectivity and had taken out a patent for a receiver incorporating capacity and self-induction and capable of being tuned.

The next step, also to be attributed to Marconi, marked the beginning of trans-Atlantic wireless communication. Marconi made use of an elevated aerial connected through a spark gap to earth. The waves generated were consequently in a vertical plane and could travel great distances before becoming attenuated by the earth's resistance. He arranged for a powerful series of signals to be sent out from a station in Cornwall and he himself went to Newfoundland to try to detect them. The experiment was a complete success, and demonstrated that the waves would follow the contour of the earth, a fact which was afterwards explained by the theory of the Heaviside layer. This acts as a kind of whispering gallery and reflects the waves impinging on it.

So far, signalling had been confined to discontinuous trains of waves generated by spark transmitters, but it was realised that there would be a distinct improvement if the signals could be made to consist of modulations in amplitude of a continuous wave of definite frequency, the modulations recurring with a frequency of their own.

The first experimenter to achieve this was Duddell, using an electric arc as part of a circuit containing capacity and inductance. So long as the circuit was not interfered with, the note emitted by the circuit was of uniform tone, but it could be varied by alteration of the self-induction or capacity by means of a key. Duddell's arc responded only to low frequency vibrations and was not applicable to the extremely high frequency vibrations needed for effective transmission. Poulsen improved the arc by immersing it in hydrogen under various pressures, and finally obtained an arc of really high frequency, which he patented in 1903.

There still remained the problem of detecting such waves. In 1904, Fleming perceived that the rectifying action of the two electrode valve could be adapted for the detection of ether waves, and he patented the vacuum valve as a detector. At first the valve was only used for the discontinuous system of spark signalling. Later, Fessenden devised the heterodyne system of reception, in which he superimposed on the received wave another of nearly the same frequency, producing low frequency beats which could be detected by the valve and made to operate a telephone. It was now possible to superimpose on a continuous wave the modulation of the human voice, applied by a microphone, and to detect the resulting vibrations at a distant station. This was the beginning of wireless telephony.

The amount of energy received at a station was small and the signals therefore feeble. De Forest conceived the idea of introducing the grid into a valve and supplying the latter with energy from a local high-tension battery. The pulsations of the received wave were applied to the grid, which therefore acted as a regulator, sometimes assisting the flow of current in the valve and sometimes retarding it. The energy of the signals received was supplied by the local battery, the grid merely acting as a relay, putting energy into the disturbance, but not otherwise interfering with it. It was soon found that the three electrode valve could be used for generating continuous waves, at the same time enhancing their power enormously. Thus in 1913 it became feasible to transmit speech and music to great distances.

In 1917 there was further development when the remarkable property of quartz was utilised to control the frequency of transmitted waves. If a crystal of quartz is compressed it becomes polarised, while on the other hand if it is electrified it constricts. This reversible action renders quartz a natural intermediary between mechanical and electrical vibrations. Eccles uses the vibrations of quartz as a transmitter for electrical waves of steady frequency. This frequency is regulated by a tuning-fork adjusted to the frequency desired and operating on a piece of quartz so as to generate waves of the same frequency. After amplification, signals of enormous power can be sent out with a precision of tuning hitherto unequalled. Broadcasting on a large scale was thus made possible. It was initiated in the United States in 1920 and in Great Britain in October 1922.

Beyond the Milky Way.*

THE star-system best known to us is the Galactic system, which is bounded by the Milky Way. About two million such systems of stars can now be observed; they are known as extra-galactic nebulæ. A random collection of extra-galactic nebulæ seems at first to show a bewildering variety of size, shape, brightness, and constitution, but a scientific study soon reduces them to law and order. Rejecting all those which are not seen edge on, we find that by far the greater number of the remainder can be arranged in a single continuous sequence, beginning with spheres and ending with flat discs. Since the speed of rotation of a body increases as it shrinks, it seems likely that we may interpret this sequence of nebulæ as one of different stages of development or evolution. If this conjecture is sound, a nebula starting with little rotation at first and shrinking in size would gradually increase its speed of rotation as it shrank, and would move steadily along the sequence as it did so.

The way to test this conjecture is to calculate for ourselves how a mass of rotating gas would change in shape as it condensed and shrank. Although the mathematical analysis is not simple, and cannot be absolutely precise, it is fairly conclusive; we find that the evolution of a mass of rotating and shrinking gas would be represented exactly by passage along the sequence.

---

* Substance of an evening discourse delivered before the British Association, London, on Sept. 29 by Sir James Jeans, F.R.S.

How did the nebulæ themselves come into being? The conjecture which at once jumps to the mind is that the nebulæ may have been formed by the same process as the stars; just as the stars came into being as condensations in a tenuous uniformly spread gas—the outer fringes of the nebulæ—so the nebulæ may themselves have previously come into being as condensations in an earlier mass of uniformly spread tenuous gas. This can never be more than a conjecture, but there are strong arguments in its favour.

Differences in size and brightness between nebulæ of the same shape are almost entirely due to a distance effect. This makes it possible to estimate the distances of all nebulæ, even the very faintest, with fair accuracy. The faintest which can be observed photographically in the 100-inch telescope prove to be at the amazing distance of about 140,000,000 light-years. Dr. Hubble finds that the two million nebulæ which lie within this distance are fairly uniformly spaced at about 1,800,000 light-years apart. We can construct a model, by taking apples and spacing them at about 10 yards apart, until we have filled a sphere a mile in diameter. This will use about 300 tons of apples. This sphere is the part of space we can see in the 100-inch telescope; each apple is a nebula containing matter enough for the creation of several thousand million stars like our sun: each atom in each apple is as big as Betelgeux, with a diameter equal to, or slightly larger than, that of the earth's orbit.

The circumstance that the nebulæ are fairly uniformly distributed through space certainly supports the conjecture that they may have originated out of a primeval gas spread uniformly through space. Moreover, it can be proved that such a gas would not stay uniformly spread through space but would break up into condensations; and that each condensation would have something like the same mass as the observed nebulæ.

The general breaking-up process of which this is the beginning is in operation throughout the universe. It might be thought that the attractive forces of gravitation would continually draw all the broken pieces together again. The exact reverse appears to be the case. Not only is the substance of the universe for ever being broken into smaller pieces, but these pieces for ever tend to scatter farther and farther apart. Every ray of sunlight that enters our eye carries mass with it; eight minutes previously this mass was part of the mass of the sun. Every second the sun loses more than four million tons of mass in the form of sunlight and sun-heat. As the result of this continual loss of mass the sun's gravitational hold on its family of planets for ever weakens, and these are driven further off into space. The earth's orbit round the sun is not so much like a circle or ellipse as like a coiled watch-spring—a spiral for ever receding into the cold and dark of space.

The same tendency affects the galactic system as a whole. Throughout the universe, all the smaller broken pieces, satellites, planets, stars, are scattering away from one another in apparent opposition to the laws of gravitation.

Still more surprising and sensational is the recent discovery that the largest pieces of the universe—the great extra-galactic nebulæ we have been discussing—are to all appearances engaged in a similar scattering. They, too, appear to be running away from us and from one another. Until recently it was thought that on the whole the nearer nebulæ were approaching the galactic system, while the more remote were receding. We now know that the nearer nebulæ appeared to be approaching merely because they happen to lie mostly in the direction towards which the sun is being carried by the rotation of the galaxy; actually we are approaching them. After the sun's motion in the galaxy has been taken into account, all, or nearly all, of the nebulæ appear to be receding from the galaxy. The nearer nebulæ have small speeds, and the more remote nebulæ have greater speeds; in general, speed is approximately proportional to distance. This simple law seems to hold to the very farthest of the nebulæ—Hubble finds that for every million light-years of distance there is a speed of recession of about 105 miles a second. The last nebula to be investigated at Mount Wilson shows a speed of recession of 12,300 miles a second; its distance, as estimated from its faintness, being about 105 million light-years.

On the face of it, this looks as though the whole universe were uniformly expanding, like the surface of a balloon while it is being inflated, with a speed such that it doubles its size every 1400 million years.

There is one strong theoretical argument in favour of regarding the apparent speeds as real. Einstein's original cosmology regarded the universe as being as full of matter as a universe of its size could possibly be without violating the theory of relativity. Recently, Lemaître, of Louvain, has shown that a universe of this type would not be static—there would be an unstable quality about it. The condensation of the primeval gas into distinct nebulæ, and the imprisonment of a large part of the free energy of the universe in these nebulæ, would cause it to start expanding, in which case it would continue to expand, its radius finally increasing exponentially with the time, until it ended up as an empty universe—finite matter spread through infinite space. Throughout the motion the relative speed of recession of any two nebulæ would be exactly proportional to their distance apart, so that, at first glance at least, this theory seems exactly to fit the observed facts. It not only provides a suggestion as to why the nebulæ may be receding. It goes much further, and predicts that they must be receding; if Einstein's relativity cosmology is sound, the nebulæ have no alternative—the properties of the space in which they exist compel them to scatter.

Yet various circumstances suggest a need for caution. For one, the speeds of the nebulæ are not strictly proportional to their distances. Again, the very magnitude of the apparent speeds casts doubt on their reality; they would reduce the whole existence of the universe to a mere flash—at any rate in comparison with what we have recently believed. If they are real, Eddington has calculated that the universe must have started from a radius of about 1200 million light-years, and that its total mass must be about $2 \cdot 3 \times 10^{55}$ gm. which is the mass of $1 \cdot 4 \times 10^{79}$ protons and an equal number of electrons. So far as we can tell from the masses of the extra-galactic nebulæ, the present average density of matter in space appears to be not less than 10^{-30} gm. per c.c., which, with the same amount of matter, would assign a radius of 13,200 million light-years to the universe—only eleven times its initial value. If the motions are real, the universe is only at the beginning of its career; as it appears at present to be doubling in size every 1400 million years, the few doublings which these figures permit cannot have occupied more than 10,000 million years at most.

General calculations on the ages of astronomical bodies point to far longer periods of time than this. The mere act of condensation of the nebulæ was probably a matter of hundreds of thousands of millions of years. Perhaps there is no real difficulty here; it might well take this long to get the doubling process really going. The real difficulty is that the stars carry intrinsic evidence of having lived through far longer periods than this.

Spectroscopic binaries provide further evidence. Observation reveals a complete sequence; it begins with systems which appear to have just broken into two as the result of rotation—pairs of stars describing circular orbits, and almost in contact—and ends with systems in which the two stars are far apart and describing elliptical orbits. Theory suggests that this observational sequence exactly depicts the evolution of a star which has broken into two as the result of excessive rotation. The outstanding importance of this sequence to our present discussion lies in the fact that the stars at the beginning of the sequence are undoubtedly many times more massive than those at the end. It seems likely that those which are now at the end must have begun at the beginning and lost the greater part of their mass in the form of radiation, and to do this would take millions of millions of years.

Considerations such as these make it very difficult to believe that the universe can be such an ephemeral concern as the apparent speeds of recession of the nebulæ would suggest.

Birthdays and Research Centres.

Oct. 5, 1861.—Sir THOMAS HEATH, K.C.B., K.C.V.O., F.R.S., honorary fellow of Trinity College, Cambridge, Joint Permanent Secretary to the Treasury, 1913–19, and Comptroller-General of the National Debt Office, 1919–26.

Having published my "Manual of Greek Mathematics" in the early part of this year, I am continuing my life-study of Greek mathematics and astronomy, with the view of keeping pace with the new discoveries in that and allied fields which are continually being made. Thus it is that I was able to include in the "Manual" some interesting things that have come to light since the publication in 1921 of the "History of Greek Mathematics"; for example, an investigation by Archimedes of the problem of inscribing a regular heptagon in a circle (preserved in an Arabic treatise) and some very remarkable results of the study of Babylonian cuneiform inscriptions of 2000–1800 B.C.

I have long wished to write upon the mathematical passages of Aristotle, and hope to proceed with that work if circumstances permit.

Oct. 9, 1863.—Prof. A. C. SEWARD, F.R.S., professor of botany in the University of Cambridge.

Since the publication in 1925 of two papers on Cretaceous plants collected in Greenland by Mr. Holttum and me ten years ago, I have been working through a large consignment of fossils sent to me through the courtesy of colleagues from the museums of Copenhagen and Stockholm. With the help of the additional data thus obtained, I hope to complete in the near future a supplementary account of the rich Cretaceous floras of western Greenland. In this work much assistance has been received from junior co-workers.

Other lines of work are: a more systematic consideration of the bearing of palæobotanical data on the general problem of evolution; and a more critical study of the geographical distribution of plants during the several geological periods.

One of the subjects which I would recommend for treatment is a careful revision of European collections of Tertiary plants.

Oct. 10, 1893.—Prof. M. SAHA, F.R.S., University professor of physics, Allahabad.

The Physical Laboratory of the University of Allahabad is one of the oldest and smallest laboratories in India, having been established about thirty years ago, but little research work was done before I took charge in October 1923. Since then, my colleagues and I have been trying our best to organise the laboratory for research work, but I must confess that I am not satisfied with the progress so far made. Research work is being carried on chiefly in spectroscopy and X-rays. At present we are engaged in studying the absorption spectrum of saturated halides of multivalent elements, and on the modification of quanta by photo-ionisation. The work on thermal ionisation has been temporarily suspended owing to lack of space and time. Research students are engaged in the classification of spectral lines. There is a wireless section, with a good broadcasting station, and it is planned to undertake work on propagation of radio in India, but nothing has been achieved, in so far as the co-operation of other universities could not be secured. The staff (total strength, nine) is heavily overworked, as there are about 200 undergraduate and 25 advanced students, and the laboratory is too much congested, for there has been practically no extension since its foundation.

Societies and Academies.

LONDON.

Institute of Metals, Sept. 15* (Annual Autumn Meeting, Zurich).—**W. E. Alkins**: Experiments in wire-drawing. (2) Notes on the relation between reduction of area by cold-drawing and tensile strength of H.-C. copper. Annealed copper rod 0·435 in. diameter was drawn through straight-sided tapering dies at single drafts of slowly increasing amount. The resulting 'primary' tensile strength reduction of area curve consists of an approximately rectilinear portion up to about 15 per cent reduction and of a smooth curve concave to the reduction axis from 15 per cent upwards. Below 15 per cent, results are consistent with the view that drawing takes place by simple elongation under tensile stress; above 15 per cent the curve has the form of a rectangular hyperbola, and one asymptote appears to lie suggestively near the limiting tensile strength to which copper can be cold-drawn.—**Clement Blazey**: Brittleness in copper. The experiments described are a continuation of those described in two other papers already published under the title of "Brittleness in Arsenical-Copper". It has been found that the brittleness is not restricted to arsenical-copper, but may be produced in copper free from arsenic.—**Edward J. Daniels**: The attack on mild steel in hot-galvanising. Experiments have been carried out in the laboratory to determine the rates of attack on mild steel strip when immersed in different brands of zinc at various temperatures between 432° C. and 540° C. The influence of the addition of small percentages of aluminium, antimony, and tin has been investigated, and the action of alloys of zinc and cadmium has also been studied.—**J. S. Dunn**: The oxidation of some copper alloys. The zinc-copper alloys fall, so far as their behaviour under oxidation is concerned, into two classes, fairly sharply separated. Those with copper contents below about 80 per cent all oxidise at essentially the same rate, and all give rise to an oxide which is almost pure zinc oxide.

---

* Continued from p. 554.

Those with copper above about 86 per cent oxidise at approximately the same rate as copper, and the oxide contains the metal in the same proportion as the original metal. The rate of oxidation increases exponentially with temperature, doubling itself approximately for every 75° C. rise in temperature.—**W. R. D. Jones**: The copper-magnesium alloys. (4) The equilibrium diagram. Magnesium and copper form solid solutions to a limited extent. At the ordinary temperature 0·02 per cent copper is soluble in magnesium and 2–2·2 per cent magnesium in copper. Two compounds, Mg_2Cu and $MgCu_2$, exist which do not form solid solutions, but form eutectic series with each other and with the solid solutions of copper with magnesium, and of magnesium in copper. The compound MgCu is not formed in the solid state.—**Hugh O'Neill**: Note on the diameter measurement of certain Brinell indentations in cold-rolled metal. Diameter measurements of the indent may differ by 3-4 per cent according to whether vertical or oblique illumination is used with the measuring microscope.—**Hugh O'Neill and J. W. Cuthbertson**: The work-hardening capacity and elongation properties of copper. So far as they go, the results indicate that (*a*) the Tetmajer 'uniform elongation' value, and (*b*) the 'extensibility', that is $(1+a)$, where a is the index in the Bertella-Oliver elongation equation, are reliable measures of the work-hardening capacity of a metal.—**C. J. Smithells, S. V. Williams, and E. J. Grimwood**: Melting nickel-chromium alloys in hydrogen. Sound ingots can be produced by this method, provided that all the oxides present in the melt are reduced by hydrogen before casting. Alloys prepared from commercial materials give better resistance to oxidation than those prepared from pure materials. The probability that the presence of certain impurities has a beneficial effect was confirmed by making deliberate additions of elements known to be present as impurities in the raw materials. The process of hydrogen melting of nickel-chromium alloys is being applied on a commercial scale. The process has also been used with success for the preparation of other metals and alloys in a ductile state without the use of the usual deoxidisers.

ROME.

Royal National Academy of the Lincei, Feb. 15.—**U. Cisotti**: Circulations about regions of dead water limited by a polygonal wall and by a free surface.—**L. Cambi and A. Cagnasso**: A new series of nitrososulpho-salts of iron: nitrosodithiocarbamates. Treatment of a solution containing $Fe(NO)SO_4$ with the aqueous solution of a dithiocarbamate results in the immediate formation of an emerald-green nitroso-salt of the general formula $(R_2N.CS.S)_2Fe.NO$. These compounds, several of which have been prepared and analysed, appear to be ferric nitrosodithiocarbamates, but their constitution has not yet been definitely established.—**G. Dantoni**: The definition of integrals.—**R. Caccioppoli**: Linear functionals in the field of analytic functions.—**R. Calapso**: A theorem on Green's angle.—**E. Gugino**: The behaviour of the forces of reaction in the motion of any material system acted on by positional forces.—**G. B. Bonino and L. Brüll**: Raman spectrum and chemical constitution of certain chloroethylenes. In a recent study of the ultra-red molecular spectrum of ethylene, Mecke classified the frequencies of the oscillations characteristic for the molecule of this hydrocarbon into valency and deformation oscillations. For tetrachloroethylene, the symmetry of which is similar to that of ethylene, the ratios between these frequencies are calculated to be

$$\sqrt{\frac{2}{\mathrm{C}+2\mathrm{Cl}}}:\sqrt{\frac{1}{2}\left(\frac{1}{2\,\mathrm{Cl}}+\frac{1}{\mathrm{C}}\right)}:\sqrt{\frac{11}{2\,\mathrm{Cl}}}=1{\cdot}31:1{\cdot}85:1,$$

the values obtained by Pringsheim and Rosen being 1·45 : 1·91 : 1. The cis- and trans-isomerides of 1 : 2-dichloroethylene are also considered.—**A. Quilico and M. Freri**: Azopyrrole blacks (3). For certain of the black products formed from pyrrole and diazo-compounds as the result of a complicated process of oxidation and coupling, attempts are made to establish the number of pyrrole and phenyl nuclei taking part in the condensation, and a hypothesis concerning the general lines of their structure is advanced.—**A. Debenedetti**: Determination of the optic axial angle of biaxial minerals by means of Fedorow's plate.—**G. Tallarico**: The biological value of the products of manured or artificially fertilised soil. Experiments with turkeys show that the birds given a vegetable diet grown on manured land are more resistant to disease than those fed on material grown on soil artificially fertilised.—**Ada Bolaffi**: Certain lipoidal fractions of the adenocarcinoma of the rat.—**G Armellini**: Memorial notice of P. G. Hagen.

SIDNEY.

Linnean Society of New South Wales, July 29.—**W. J. Dakin**: On a new bopyrid parasite from the coast of New South Wales. Description of a new genus allied to the group *Orbione*, *Parapenæon*, and *Epipenæon*, the type species being an ectoparasitic branchial parasite under the branchiostegites of a penæid prawn, *Aristeus foliaceus*.—**J. R. Malloch**: Notes on Australian Diptera (28). Data on the occurrence of the family Rhagionidæ in Australia. A key is given to the genera of the family.—**G. H. Cunningham**: The Gasteromycetes of Australasia (12). The genus *Scleroderma*. The genus is represented in this biological region by five species, of which *S. australe* and *S. radicans* are confined to Australia, *S. flavidum* extends to Africa and North America; and the other two species, *S. Bovista* and *S. verrucosum*, have a general distribution. A general account is given of the morphology and development of the genus, as well as an artificial key to the species.

Diary of Societies.

FRIDAY, October 2.

Institution of Chemical Engineers (at Chemical Society), at 6.—N. E. Rambush and F. F. Rixon: The Gas Generator as a Direct Producer of Metallurgical Products.

Society of Chemical Industry (Manchester Section) (at Engineers' Club, Manchester), at 7.—Dr. T. Callan: Selected Chapters in Organic Analysis (Lecture).

Junior Institution of Engineers, at 7.30.—R. P. Mears: Submersible Bridges on Indian Roads.

SATURDAY, October 3.

Gilbert White Fellowship (at 6 Queen Square, W.C.1), at 3.—Dr. P. Flemming: Harley Street, Historical and Topographical Notes (Lecture).

Institute of British Foundrymen (Lancashire Branch) (at College of Technology, Manchester), at 4.—W. West: Low Total Carbon Cast Irons and their Service to the Foundryman.

MONDAY, October 5.

Society of Engineers (at Geological Society), at 6.—Major C. K. Cochran-Patrick: Present Practice in Aerial Survey.

British Psychological Society (Education Section) (at London Day Training College), at 6.—H. A. Simmonds: Vocational Guidance and Education.

Institution of Automobile Engineers (at Queen's Hotel, Birmingham), at 7.30.—W. A. Tookey: The Internal Combustion Engine and its Performances (Presidential Address).

British Kinematograph Society (in Gaumont British Theatre, Wardour Street), at 7.45.—T. Thorne-Baker: The Spicer-Dufay Colour Process.

Society of Chemical Industry (London Section) (at Chemical Society), at 8.—Sir Daniel Hall: Recent Applications of Science to Agriculture.

TUESDAY, October 6.

London Natural History Society (at London School of Hygiene and Tropical Medicine), at 6.30.—C. S. Bayne: Humbug in Ornithology and Entomology.

Iron and Steel Institute (jointly with Lincolnshire Iron and Steel Institute) (in Modern Schools, Scunthorpe), at 7.—B. Matuschka: Solidification and Crystallisation of Steel Ingots: the Influence of the Casting Temperature and the Undercooling Capacity of the Steel.—A. Robinson: Melting Shop of the Appleby Iron Co., Ltd.—Dr. W. Rosenhain and A. J. Murphy: Accelerated Cracking of Mild Steel (Boiler Plate) under Repeated Bending.

WEDNESDAY, October 7.

Pharmaceutical Society of Great Britain, at 3.—Prof. G. E. Gask: Inaugural Address and Presentation of the Pereira Medal.

Institute of Fuel (jointly with other Societies) (at Institution of Electrical Engineers), at 7.—Dr. W. R. Ormandy: Coal: Smokeless Fuel and Oil from the National Standpoint.

Society of Public Analysts and other Analytical Chemists (at Chemical Society), at 8.—J. C. Maby: The Identification of Wood and Wood Charcoal Fragments.—Dr. T. Callan and N. Strafford: The Examination of Dyed Leathers in Cases of Alleged Dermatitis.—Dr. W. L. Davies: The Determination of Chlorides in Dairy Products and Biological Material.

THURSDAY, October 8.

Institution of Automobile Engineers (at Merchant Venturers' Technical College, Bristol), at 7.—W. A. Tookey: The Internal Combustion Engine and its Performances (Presidential Address).

Institute of Marine Engineers (Junior Section), at 7.—J. R. Douglas: The Running and Maintenance of Marine Turbines.

Institute of Metals (London Local Section) (at 83 Pall Mall), at 7.30.—W. T. Griffiths: Chairman's Address.

Royal Aeronautical Society.—Prof. Piccard: Experiences in his Balloon Ascent.

FRIDAY, October 9.

Institute of Metals (Sheffield Local Section) (jointly with Sheffield Society of Engineers and Metallurgists) (in Applied Science Department, Sheffield University), at 7.30.—Dr. W. Rosenhain: Gases in Metals.

Institution of Production Engineers (at Society of Motor Manufacturers and Traders, 83 Pall Mall), at 7.30.—Annual General Meeting.

Society of Chemical Industry (Chemical Engineering Group) (at Chemical Society), at 8.—D. M. Wilson: The Manufacture and Testing of Asphalt Paving Material.

PUBLIC LECTURES.

MONDAY, October 5.

Royal Institute of Public Health, at 4.—Dame Louise McIlroy: Recent Researches in the Prevention of Maternal, Fœtal, and Neo-natal Mortality (Harben Lectures). (Succeeding Lectures on Oct. 6 and 7.)

University of Bristol (in Wills Physical Laboratory), at 5.15.—Prof. Niels Bohr: Space-Time Continuity in Atomic Physics (Henry Herbert Wills Memorial Lecture).

TUESDAY, October 6.

King's College, London, at 5.—Dr. J. W. Pickering: Blood Plasma and Platelets. (Succeeding Lectures on Oct. 13, 20, and 27.)

Gresham College, at 6.—Sir George Newman: Physic. (Succeeding Lectures on Oct. 7, 8, and 9.)

SATURDAY, October 10.

Royal Institute of British Architects, at 3.—C. Williams-Ellis: Architecture? What's the Use?

Horniman Museum (Forest Hill), at 3.—Miss M. A. Murray: Egyptian Beliefs in the Hereafter.

Mathematical Association (London Branch) (at Bedford College for Women), at 3.—B. C. Wallis: Arithmetic from the Examiner's Point of View.

CENTENARIES.

Friday, October 2.

James Clerk Maxwell Centenary Celebration (at Cambridge).

Friday, Oct. 2 (*morning*).—Addresses by Prof. Max Planck, Sir Joseph Larmor, and Prof. Niels Bohr.

(*Afternoon*).—Addresses by Dr. William Garnett, Sir Ambrose Fleming, and Sir Oliver Lodge.

Friday, October 9.

Michael Faraday Centenary Celebration (in City Hall, Newcastle-upon-Tyne), at 7.—Dr. W. M. Thornton: Faraday and his Successors—the Growth of an Idea.

CONGRESS.

October 5 to 10.

Congress on Tuberculosis (at Davos).—*Principal Subjects for Discussion*:—Development and Course of Tuberculosis of the Lungs; Extra-Pulmonary Tuberculosis; Collapse Therapy.

SATURDAY, OCTOBER 10, 1931.

International Aspects of Agriculture.

IT is sometimes said that agriculture is no subject for internationalism. Indeed, this dictum was not infrequently hurled at those who, after the War, made the first tentative attempts to start or to revive the international handling of agricultural problems. Oblivious of the fact that the produce markets of the great countries were becoming, with a decisive rapidity which was leaving all arguments in the rear, scenes of the most bitter struggles of international competition, the old-fashioned agriculturist was still arguing up to a few years ago—and in a few cases even continues so to argue to-day—that the knowledge and practice of each country are all-sufficient for that country. This point of view has not been without its influence on the research side of the subject. It has certainly affected in no small degree the study of the best means of getting the results of the experiment stations adopted in practice.

The doctrine of national self-sufficiency in matters agricultural has wrought deep havoc particularly on the social side of agricultural life. It is greatly delaying the fruitful interchange of social experience between the agriculture of different parts of the world. Wherever it has been broken down the results bid fair to be beneficial, and it is to the advantage of European agriculture that it has been able to revive and to place on a hopeful basis a body which even before the War stood for the international idea among research workers and also among practical farmers. The Fifteenth International Agricultural Congress recently held at Prague under the auspices of the International Commission of Agriculture went with a swing, and reflected great credit on a body which seems genuinely representative of large sections of European agriculture, even if it has not yet managed to secure adequate representation from Great Britain, Australia, or the Americas.

The International Commission of Agriculture stands for independence from government action. It is of course accustomed to work in friendly relations with the great State organisations which handle agriculture on an international footing, such as the League of Nations, the International Labour Office, and similar bodies. Indeed, one of its most important functions is to help in conveying the opinions of the research and of the farming world to these and other official organisations, in which effort it has been singularly successful of recent years, as all can testify who have followed its activities since 1927, the year of the World Economic

Conference convened by the League of Nations at Geneva. But it does not profess to resemble these official institutions, and guards most jealously its essential prerogative of opinion and action independent of all government influences.

Men of science can only view with sympathy ideals such as these. What the International Commission of Agriculture is now trying to accomplish from the practical farmers' point of view—to focus and to harmonise world opinion on world problems—pure science has always tried to do in its own magnificent field. It has had one great advantage. If practical agriculture has too frequently been wrongly argued to be a national craft, then science, as has always been admitted, is from its very nature international. Even popular opinion now endorses this view; elementary textbooks do homage to it.

Nor has science in any way improperly disowned its world character when joining hands with agriculture. However frankly and rightly agricultural experiment stations and demonstration farms have been financed and controlled by national authority and for national ends, their results have been yielded up for the good of all. No trade secrets are possible for the investigator of agricultural science so long as that profession follows in the footsteps of the workers in pure science.

There is, however, a shadow side to this free trade in intellect; it leaves the intellectual, after years of labour, with an empty purse. No government and no institution responsible for experimental work in the sciences bearing on agriculture can afford to pay salaries on so handsome a scale as to be at all commensurate with those massive rewards which sometimes accrue to the authors of mechanical and other inventions capable of being patented and then exploited by private enterprise. While this does not deter the man with a genius for biological investigation, it undoubtedly affects adversely the recruitment of biological students. Prof. T. G. Hill admitted this difficulty in his presidential address to Section K (Botany) of the British Association in referring to the present dearth in the British Empire of trained botanists for administrative and technical services when he said the work must be its own reward.

Such disadvantages are met with in the whole profession of science, but apply with particular force to the biological scientific career. While, however, in other departments of science some alternative reward, principally of reputation, fame, and distinction, comforts the soul of the investigator, the agricultural investigator appears to share very markedly neither in the honours which fall to academic science nor in the material rewards of commerce. The irony of the position is that successful work of the kind which he undertakes may spell not merely thousands to a few individuals but positively millions to a whole country. In his recent presidential address to Section M (Agriculture) of the British Association, Sir John Russell stated that, by using improved methods of cultivation, the farmers of Victoria, Australia, now obtain one bushel of wheat for each inch of rain falling during the season, whereas forty years ago they obtained only half a bushel. In Java the Dutch have produced a new sugar cane which has quadrupled the output of sugar. The production and use of artificial fertilisers in the past thirty years have changed completely the problem of the world's food supply, while the figures as to the great national wealth created by new agricultural strains of wheat, such as Marquis in Canada and the United States, run into sums of astronomical dimensions.

It would, therefore, seem a simple act of justice and of wise policy to arrange that some encouragement should occasionally be held out to the agricultural inventor. That such reward should be international in character would also appear to be thoroughly appropriate when we remember the universal application of most great agricultural advances. It thus becomes pertinent to direct attention to a recent highly interesting suggestion put forward by the Secretary-General of the Czechoslovak Academy of Agriculture, Dr. Edouard Reich, which might serve the end contemplated. Simultaneously with the Fifteenth International Congress of Agriculture already referred to, though not directly in connexion with it, the Czechoslovak Academy of Agriculture, which is a research and educational institution serving the needs largely of countries in eastern and central Europe, held a meeting of its corps of foreign members. At this meeting, Dr. Reich put forward various suggestions designed to further international co-ordination of scientific and intellectual effort applied to the agricultural domain. Among these suggestions was one for the foundation of a prize in agriculture. It was estimated that an endowment fund of about £10,000 would have to be collected by subscription. It is much to be hoped that the organising committee of distinguished men of science and other workers who were elected to deal with the proposals put forward at the meeting will be able to work out the details and carry them into practical effect.

The Biological Nature of the Viruses.[*]

By Dr. H. H. DALE, C.B.E., Sec.R.S.

THE viruses are a group of agents, the existence of which would certainly be unknown to us but for the changes produced by their presence in the bodies of higher animals and plants. They seem to have one property at least of living organisms, in being capable, under appropriate conditions, of indefinite reproduction. We know nothing of their intrinsic metabolism : it has even been asserted that they have none. Few of them have yet been rendered visible by the microscope ; it is, indeed, a question for our discussion whether any of them have yet been seen or photographed. It is a question, again, whether any of them, or all of them, consist of organised living units, cells of a size near to or beyond the lowest limits of microscopic visibility ; or whether, as some hold, they are unorganised toxic or infective principles, which we can regard as living in a sense analogous to that in which we speak of a living enzyme, with the important addition that they can multiply themselves indefinitely. Some, however, would attribute this, not to actual self-multiplication, but to a coercion of the infected cells to reproduce the very agent of their own infection.

The problems presented by the nature and behaviour of the viruses cannot fail to raise questions of the greatest interest to anyone concerned with general physiological conceptions. What is the minimum degree of organisation which we can reasonably attribute to a living organism ? What is the smallest space within which we can properly suppose such a minimum of organisation to be contained ? Are organisation, differentiation, separation from the surrounding medium by a boundary membrane of special properties, necessary for the endowment of matter with any form of life ? Or is it possible to conceive of a material complex, retaining in endless propagation its physiological character, as revealed by the closely specific reaction to it of the cells which it infects, though it is not organised into units, but uniformly dispersed in a watery medium ? Among those who study the viruses primarily as pathogenic agents, these questions provide matter for debate ; I suggest that they are questions with which the physiologist may properly be concerned.

I cannot deal with the history of the subject ; but it is of interest to note that Edward Jenner was dealing, in small-pox and vaccinia, with what we now recognise as characteristic virus infections, long before there was any hint of the connexion of visible bacteria with disease. Pasteur himself was dealing with another typical case of a virus infection in the case of rabies. The clear recognition, however, of the existence of agents of infection, imperceptible with the highest powers of ordinary microscopic vision, and passing through filters fine enough to retain all visible bacteria, begins with Ivanovski's work in 1892 on the mosaic disease of the tobacco plant, brought to general notice and greatly developed by Beijerinck's work on the same infection some seven years later ; and with Loffler and Frosch's demonstration, in the same period, that the infection of foot-and-mouth disease is similarly due to something microscopically invisible, and passing easily through ordinary bacteria-proof filters. Since those pioneer observations the study of viruses has spread, until they are recognised as the causative agents of diseases in an imposing and still growing list containing many of the more serious infections of man, animals, and plants.

If we are to discuss the biological nature of the viruses, it is obvious that we should begin by attempting some kind of definition. What do we mean by a virus ? And what are the tests by which we decide that a particular agent of infection shall be admitted to, or excluded from, the group ? But a few years ago I think that we should have had no difficulty in accepting three cardinal properties as characterising a virus, namely, invisibility by ordinary microscopic methods, failure to be retained by a filter fine enough to prevent the passage of all visible bacteria, and failure to propagate itself except in the presence of, and perhaps in the interior of, the cells which it infects. It will be noted that all three are negative characters, and that two of them are probably quantitative rather than qualitative.

Such a definition is not likely to effect a sharp or a stable demarcation. We shall see that its failure to do so is progressive. Nevertheless it would still be difficult to refuse the name of virus to an agent which fulfils all three criteria ; and we must therefore, in consistency, apply it, on one hand, to the filtrable agents transmitting certain tumours, and, on the other hand, to the agents of transmissible lysis affecting bacteria, and now widely known and studied as bacteriophages. But the strict application of such a definition, based on negative characteristics, must obviously narrow its scope with the advance of technique. We may look a little more closely at the meaning of these different characters.

Microscopic visibility is obviously a loose term. Rayleigh's familiar formula, in which the lower limit of resolution is equal to one-half the wavelength of the light employed, divided by the numerical aperture of the objective, only gives us the smallest dimensions of an object, of which, with the method of transmitted illumination habitually used in former years, a critical image can be formed. There can be no doubt that the separate particles of practically all the agents to which the term virus would be applied fall below this limit of size. To put it in plain figures, their diameter is less than 0·2 micron. On the other hand, progress has recently been, and continues to be, rapid in the direction of bringing into the visible range minute bodies associated with a growing number of viruses. This has been effected, on one hand, by improvement in staining technique, which probably owes its success largely to increase of the natural size of the particles by a deposit of dye on their surface; and, on the other hand, by forming visible diffraction images of the unstained particles with wide-aperture dark-ground condensers, and by photographing the images formed of them with shorter invisible rays. Mr. Barnard has obtained such sharp photographic images of the bodies associated with one virus, measurements of which give their natural size by simple calculation.

---

[*] From the presidential address introducing a discussion on the subject in Section I (Physiology) of the British Association in London on Sept. 28.
